For the treatment of symptoms, he recommended compression of the abdominal walls for shock, teaspoonful doses of hot water for thirst, and if the pain was excessive opium might be given. If possible he considered opium should be avoided, as it masked the symptoms and obscured the diagnosis. If it had to be given, morphine, gr. ⅓, subcutaneously was better than opium by the mouth. The speaker said that Colonel Senn, U. S. A., urged early operation, but only when distinct evidence of visceral lesion was present. To assist diagnosis Colonel Senn used inflation of the intestine with hydrogen gas, a pressure of two and one-half pounds per square inch being used if needful, the patient of course being anæsthetized. If perforation were present the gas escaped by the abdominal wound. If evidence of perforation was forthcoming, expectant treatment held out little hope. In the war of 1870–71 the mortality was ninety-eight per cent. in these cases. Wounds of the large intestine were not so fatal as those of the small, possibly due to being in part extraperitoneal. He held that the proper time to perform laparotomy was the earliest possible moment after diagnosis of penetration of the abdominal cavity. If, when a projectile entered the abdomen, in only four or five per cent. of cases the viscera were injured, one might wait; but as the figures were the other way about, and since after penetration the viscera were almost always injured, immediate operation gave the best results. After twelve hours' delay the chances were against recovery, and twenty-four to forty-eight hours' delay was hopeless. Profound shock and collapse, unless due to hemorrhage, might be considered as contraindications. When the patient had rallied from the primary shock, the wound should be examined, enlarging it slightly if needful, to determine the fact of penetration. Only the finger, and no instrument, should be used. If penetration had occurred the abdomen should be opened and all effused blood removed, and bleeding points sought for and secured. Any wound of the intestinal tract should next be attended to, bearing in mind that the more nearly the bullet had traversed the abdomen from side to side the greater was the number of perforations likely to occur. And as a fatal result might follow overlooking only one perforation in many, the examination must be as complete as possible. Each perforation as discovered must be dealt with by simple suturing by Lembert's method or by resection. Resection was called for when the loss of substance in the tube would cause a diminution of its calibre by one-third, when several perforations existed close together, and when the mesenteric edge was implicated.

Suturing when simple must be done at right angles to the long axis of the gut, to prevent constriction. The best material for suturing the serous coat was fine China silk previously boiled, and thin catgut for the mucous coat. A Milhiser's round needle with a somewhat blunt point is best. Ten Lembert's stitches should be used to the inch. For circular enterorrhaphy the Czerny-Lembert suture should be used, with catgut for the first and China silk for the second line.

The major operations on the intestines in these cases are nearly always excisions of portions of the tube, or end-to-end anastomoses. What was required was a water-tight seam, made by some quick method. Direct methods such as Mannsell's were mentioned; the additional incision here required was an objection. Of indirect methods he thought highly of Murphy's button on account of its rapidity. Its use requires practice and experience, however, or too much sloughing might result. The abdomen should be well flushed with sterile fluid at 105° F. and drained for from twenty-four t forty-eight hours with Keith's tubes or capillary gauze drains. The results of laparotomy for gunshot wounds in the last three wars were not encouraging, but considering the conditions, and the mortality if the cases were let alone, they were no contraindication. In the Spanish-American war all died; in the Greco-Turkish war one case of hemorrhage resulted in recovery; one patient with injury to the liver recovered, and one with wound of the hollow viscera died. In the Afridi campaign five cases were operated on, and all had fatal results.

In conclusion he would like to elicit opinion in two points: Was mere penetration ground for operating and what was the best way to restore continuity of the intestinal canal?

Dr. J. Ward Cousins said that the question had been asked whether we should operate so soon as a diagnosis was made. He thought not. The diagnosis was not easy, there might be no injury of the internal viscera, yet much collapse The action taken must depend on the judgment of the individual surgeon. If no operation was done he was not prepared to take such a gloomy view of these cases as Colonel Stevenson. The incision should be made through the point of penetration, so as to expose the tract of the bullet on account of charring, etc. Manipulation should be very gentle, and the wound should not be dilated by means of hard retractors, but held apart by stout threads. He preferred fine boiled silk for intestinal suturing. He considered wounds of the intestine far more serious than those of the stomach.

Dr. Barry Blacker suggested the use of the *x*-rays in these cases to localize the site of the bullet, which combined with the position of the wound of entry might afford evidence of the amount and site of the injury. Difficulties were met with in these cases, as owing to the abdominal movements the shadow of the bullet was often blurred and ill-defined.

Major W. C. Beevor said when visceral injury was diagnosed in civil life the rule should be to operate, but in warfare the conditions had to be taken into account. He described the conditions during a skirmish in the late Afridi campaign. The only available water was a soupy mixture probably containing urine and fæces, from a fetid village pond. The antiseptic dressings were dusty from a long mountain march, and would have to be handled by dust-begrimed men. Primary operation done under such circumstances must have resulted in infection. As illustrating the difficulty of diagnosis, he related a case in which a major of the Gordon Highlanders received a wound from a ricochet bullet, which presented the characters of a penetrating wound of the abdomen. After a time the shock passed off and the patient was able to walk and crawl half a mile to the dressing station. No operation was adopted, and the officer made an excellent recovery. In another case a bearer was shot in middle line, about one and one-half inches above the umbilicus. He fell and was left as dead by his comrades. Subsequently he was picked up by the medical officers and ordered to be carried to the main body. His carriers under fire deserted him and he managed to rejoin the main body two days later. When seen there was a piece of omentum the size of one's fist protruding from the wound. This was ligatured and cut off and the abdomen was irrigated, and he made an excellent recovery. Major Beevor wished especially to draw attention to the excellent effect on the collapse of the injection of hot sterilized water into the peritoneal cavity, both before operation, during operation, or afterward, through the drainage tube if one was at hand.

Mr. Damer Harrisson agreed with Colonel Stevenson that the absence of liver dulness was no certain sign of perforation. He related a case in which the anterior and posterior walls of the stomach were both perforated and both sutured, and the man recovered well. A quart of hot neutral saline solution was left behind in the abdomen, and he thought with Major Beevor that it was most beneficial in warding off shock. This case was operated on five or six hours after the receipt of the injury. He was quite in favor of immediate operation.

Mr. Clement Lucas quite agreed with Colonel Stevenson's maxims, but thought Major Beevor's remarks showed how impossible it was to hope to carry them out in military surgery in many cases. As to civil practice he thought that wounds from firearms were much on the increase, and he had prepared a resolutionre stricting the sale of firearms to be brought before the parliamentary bills committee. He emphasized the great danger of bullet wounds of the abdomen, and illustrated the same by cases. He would go so far as to say that if you want to kill a man don't shoot him in the head or chest, but shoot him in the abdomen. He had used ergotin in hemorrhage from the liver and kidney and suggested the use of it in other forms of abdominal hemorrhage. He had also noticed the improvement in the pulse during operation, when hot flushing was employed.

Dr. James Murphy agreed in condemning the use of opium. He had a very high opinion of Murphy's button.

Dr. J. Paul Bush thought no reliance could be placed on the presence of resonance in the hepatic area as a sign of perforation. He referred to the great difficulty of ascertaining whether more than one perforation existed.

Colonel Stevenson in reply said that statistics varied with the conditions under which the operations were performed, and in that respect the late examples in military surgery were unfortunate. As to the antiseptics and needful sterilizing apparatus, etc., the new equipment obviated many previously existing defects. He did not agree with Dr Cousins that the cases were difficult to diagnose. All that he maintained it was needful to ascertain was whether as a matter of fact a wound of the abdomen was a penetrating wound or not. If it was a penetrating wound he looked on wounding of the viscera as certain, and therefore the fact of penetration called for immediate laparotomy. Major Beevor's two cases were no argument against immediate operation; they were tangential wounds, in one case merely exposing omentum, in the other not injuring the abdominal contents at all. When patients recovered apart from operation he regarded the wounds as not actually penetrating.

Mr. Butlin called attention to the great difficulty in cases of wounds in the lower part of the thorax in deciding whether the symptoms were due to injury of thoracic contents or of structures below the diaphragm.

SECTION OF OBSTETRICS AND GYNÆCOLOGY

*First Day—Wednesday, August 2, 1899.*

**Conservative Gynæcology.**—Dr. George Granville Bantock, President of the Section, in a brief introductory address, said that he considered there was too great a tendency in recent years to resort to the knife in the treatment of gynæcological cases. Emmet's operation in particular had been done to death, and Emmet himself had to protest against its indiscriminate use. Some authorities proposed total removal of the generative organs for small fibroid tumors, and appeared to regard them almost in the same light as malignant growths. In his opinion a fibroid did not necessarily increase the risk of pregnanacy and childbirth; an erroneous analogy had been drawn between ovarian and fibroid tumors. He would ask, who had known an ovarian tumor to disappear? and, on the other hand, who had not heard of fibroids disappearing? In chronic inflammatory conditions of the appendages some advised their removal; he had known many such cases to result in recovery without operation, and had positive evidence in many cases of the wisdom of the advise he had given to patients years previously, not to have such operations performed. He deprecated operation either by the abdominal or vaginal route for cases of uncomplicated retroflexion. Tait had said, "When in doubt open the abdomen," but this advice had been much misunderstood. What was meant was, when disease actually existed of the precise nature of which there was a doubt, not to open the abdomen to see if disease was present. He believed that there was no evidence to support the theory of internal secretion of the ovaries, and when ovulation ceased he considered that the ovaries became useless and were only a source of danger. In operating he never left ovarian tissue when the tubes were removed. He had removed the second ovary for disease as long as eighteen years after removal of the first, and he always advised the removal of both ovaries when one was affected.

**The Treatment of Fever Following Delivery, with Special Reference to Serum Therapy.**—Dr. Herbert Spencer, professor of midwifery in University College, London, opened the discussion on this subject. He would divide fever following delivery into four classes: First, one-day fever, from engorgement of the breasts or emotional causes. The temperature went up rapidly on the second or third day with no other symptoms, relieved rapidly by a purge. Second, fever due to conditions not depending on the labor sometimes. The diagnosis of these was difficult. Among these conditions he would mention (1) influenza. He thought that this was the last thing to be thought of in this connection and that this name was sometimes used to cover real cases of puerperal fever. (2) Typhoid: he had seen cases in the puerperium which had been proved to be typhoid by a post-mortem examination, and in making the diagnosis during life he would rely on Widal's test. (3) Infection from previously existing pelvic lesions. (4) Fever due to septic infection, or true puerperal fever. This was generally due to infection by streptococci, but various organisms might cause it. He recognized three fatal forms, viz., acute general, lymphatic, and venous septicæmia. He advised a routine examination of every patient toward the end of her pregnancy, to avoid injury to the genital tract by substituting so far as possible abdominal for vaginal examination, to clear out the uterus carefully in the third stage of labor; to cleanse the hands and vulva thoroughly; to use as a lubricant perchloride in glycerin; to disinfect instruments by boiling. If attending a case of puerperal fever he believed that it was possible to make one's self safe by washing and antiseptics, and that abstention from practice did no more good. As regards the actual treatment of puerperal fever he advised thorough examination of each patient, examining the interior of the uterus. He used india-rubber gloves to avoid contamination. Any septic substance found in the uterus should be at once removed, but it was sometimes better when the substance was strongly adherent to leave it. He never used the curette, but washed out the uterus. He had tried continuous irrigation but had abandoned it, and discountenanced frequent intra-uterine douching when not followed by improvement. He did not use a gauze drain for the uterus as some advised. As regards abdominal section, he would not do it unless there was distinct evidence of localization of fluid. He thought that no medicine had a specific effect, and he deprecated the use of antipyretics; he gave tonics and stimulants freely, with fresh air, as much food as possible, alcohol in large quantities, and nutrient enemata when vomiting was troublesome. Serum therapy was not applied on a scientific basis. It had not decreased the mortality; it certainly lowered the temperature, but at present the good results were doubtful.

Dr. Arnold Lea, continuing the discussion in a paper entitled "Two Cases of Puerperal Septicæmia due to Streptococcic Infection," said that it was impossible to diagnose the bacterium causing infection from the symptoms and signs; in his two cases the kind of infection was verified by a bacteriological examination. The first case was treated by curetting and the application of carbolic acid twenty per cent., and resulted in recovery. Cover-glass preparations showed streptococci in the discharge, but not in the blood. Serum was not given. In the second case the patient was curetted early. On the tenth day the temperature was 104.4° F. Serum was given and followed by temporary improvement. Death occurred on the twelfth day. On bacteriological investigation streptococci were found in the discharge, in the uterine wall, and in the blood. He considered that a microscopical investigation must be done if this was to be scientific treatment. The infection was first purely local at the placental site, and in mild cases was limited by inflammation of the adjacent uterine wall. Streptococci did not cause fetor of the discharge. The local infection remained limited only for a few hours, so that treatment to do good must begin early He believed in the use of the sharp curette followed by the application of caustic solutions to the uterine wall.

Dr. Murdoch Cameron, of Glasgow, said that in those cases he douched with a double current tube. He did not believe in the use of serum, but believed in the curette. He thought it most important to procure sleep. He said it was possible to disinfect one's self perfectly in one hour after seeing a case of puerperal fever.

Dr. Shaw MacKenzie, of London, believed that syphilis predisposed to puerperal fever, and he would give mercury subcutaneously.

Dr. Purslow, of Birmingham, thought that it would always be almost impossible to give an authoritative opinion or accurate statistics as to the value of the serum treatment for the following reasons: Puerperal fever varied so much in severity, and the prognosis was so uncertain, most desperate cases sometimes recovering with little or no treatment. Dependence was never placed on serum treatment alone, but treatment by washing out the uterus and by drugs was always associated with it. He had found the curette to cause dangerous hemorrhage.

Dr. Inglis Parsons, of London, used the curette when the infection was local, and after curetting he swabbed the uterus with tincture of iodine. He gave quinine per rectum. He thought antipyretics were useless. Statistics were useless unless the same serum was always used and it was pure.

Dr. More Madden, of Dublin, had formed no opinion of serum treatment, but he relied on quinine, gray powder, and turpentine.

Professor Byers, of Belfast, said that puerperal fever was not becoming any less frequent even in Germany, where antiseptic principles were most observed. As regards prophylaxis, he had largely given up vaginal examinations in favor of abdominal, and thought that was a very important matter. He also dwelt on the importance of considering any fever after delivery as a serious matter, and of making a thorough examination when called to a case of sepsis. He would use a curette when the os was patulous and there was an unpleasant discharge, and breaking-down tissue could be felt in the uterus. He had not found good results from the serum treatment.

Major Peck, of the Indian medical service, found that some patients stood antipyretics better than cold packs, and had seen good done by antifebrin in five-grain doses.

Dr. Johnston, of Bradford, said that when fever set in he douched at once and used the cold pack.

Dr. Kealey thought that the mental condition had often something to do with the causation of fever, and that the reason it was more prevalent among the better classes was that they looked forward to their confinement with much more dread than did the working-class women.

Dr. Edgar Barnes, of Ryde, thought that sitting the patient up in bed soon after delivery had a good effect in allowing drainage.

Mr. J. W. Taylor, of Birmingham, said that he would like to see more collaboration between the laboratory and the bedside. It would be impossible to get any satisfactory scientific results until a bacteriological examination was made in each case.

Dr. Spencer made a brief reply, in which he deprecated the application of iodine to the interior of the uterus, as it caused clotting in the sinuses and veins.

Dr. Murdoch Cameron read a paper entitled "A Case of Rupture of the Uterus, Missed Labor, and Delivery Three Months Later."

This concluded the business of the first session.

*(To be Continued.)*

## Correspondence.

### OUR LONDON LETTER.

(From our Special Correspondent.)

OVARIAN AND RENAL CYSTS—VACCINATION WORRIES—PLAGUE—FOOD POISONS—COCKLES—HOSPITAL SUNDAY FUND—SIR B. SANDERSON, SIR M. FOSTER, SIR J. FAYRER—BRITISH MEDICAL ASSOCIATION'S ANNUAL MEETING—ECHOES FROM PORTSMOUTH—THE MALARIA EXPEDITION—EPSOM COLLEGE.

London, July 28, 1899.

The difficulty of diagnosing ovarian from other cysts was exemplified at the last meeting of the Gynæcological Society, when several members mentioned their experiences in this respect. The discussion arose in the relation of a case of a large hydronephrosis removed by laparotomy. The patient was a thin girl aged fourteen years, sent to Dr. Sunderland with a diagnosis of ovarian cyst. On opening the abdomen the tumor was found to be covered with peritoneum. Dr. Sunderland removed it by enucleation and ligaturing a pedicle containing the vessels several inches distant from the ureter, which was tied separately. The fluid, removed by tapping in the course of the operation consisted of about seven pints of urine. The flattened kidney substance could be seen at the back of the specimen shown. The patient recovered rapidly.

Mr. Furneaux Jordan said there was certainly at times difficulty in diagnosing renal from ovarian cysts. In a case he formerly reported he opened the abdomen for, as he thought, ovarian cyst. In the cyst thirty-three calculi were found. The other kidney was not examined, and the patient died forty-eight hours afterward. It was found at the post-mortem that the other kidney was also affected and contained seven calculi. It was strange that this patient had never complained of pain at all.

Mr. Bowerman Jessett related that a patient some years ago declined operation. She was passing blood and pus. This disappeared and she got well, but two years later returned with total suppression, having a large tumor on the opposite side. He operated and she recovered. Two years later still she returned with a large tumor on the same side, and again he removed several calculi. Yet another two years, and he operated for the third time, and the patient died. At the post-mortem both kidneys were found atrophied to such an extent that it was remarkable that she had been able to live, for hardly any kidney substance remained.

Dr. Heywood Smith mentioned a case that was aspirated some sixteen years ago, when the patient died two hours afterward. The autopsy showed both kidneys greatly distended and a calculus in each.

Dr. Arthur Giles mentioned a case in which not a symptom pointed to the kidney, but on operation its nature was disclosed; the renal cyst was removed and recovery followed.

Dr. Macnaughton-Jones (president) commented on the difficulties of diagnosis, and remarked that if the renal cyst was suspected it was difficult to be sure which kidney was affected—an argument in favor of abdominal section.

Dr. Purcell said other tumors than renal ones might simulate ovarian cysts. He had seen a case in which the abdomen was opened and a large tumor tapped which proved to be a distended bladder, though the nurses had declared that it had been emptied by catheterization just before. The wound of the bladder was closed and the patient recovered.

Dr. Hodgson called attention to a diagnostic sign: in hydronephrosis there was usually dulness in the flank, which is generally resonant in ovarian tumors.

The anti-vacs, like other foolish fanatics, continue to make themselves a nuisance to the community. Some of their less fanatical supporters are troublesome by asking questions in the House or calling for statistics. One member this week wanted to know in what jail certain recalcitrant guardians would be confined, and whether special privileges would be granted to ladies who had announced their determination to go to prison rather than carry out the law. So much for the conscience clause satisfying the would-be martyrs.

The outbreak of smallpox at Hull has not quite ceased. At a recent meeting the chairman of the sanitary committee complained that one hand was tied by the anti-vacs and the other by the opponents of the proposed new smallpox hospital. Yet Mr. Chaplin had stated in the House of Commons that of the eighty-three cases which had occurred sixty-two showed evidence of vaccination. The death rate of these sixty-two was 9.7, while among the unvaccinated it was 57.1. This is a lesson which is repeated with nearly every outbreak, and would perhaps do its work but for certain low papers which pander to the gambling spirit of the age and try to circulate their trash further by exploiting every fad. Their contents and their advertisements are a disgrace to the press. With regard to the smallpox question they might do some good if they would publish facts and exclude falsehoods. They might very well tell people that Ger-

many has practically stamped out smallpox. Thus the official statistics recently issued for 1897 show that there were only five smallpox deaths in the whole empire. This in a population of fifty-three millions. These five deaths occurred in five separate districts in Prussia, the other provinces not having a single one. There are plenty of other facts which might well cause serious reflections to Mr. Balfour and those who caved in to the virulent attacks of the anti-vacs.

The possible advance of plague into Europe is often discussed, and the question has found its way into *The Times*. Our sanitarians seem confident, but they are not supine. On the contrary they are arranging their precautions, and some of the port authorities are distributing information in the form of leaflets drawn up by their medical officers of health.

Two instances of suspected food poisoning have startled the public. One occurred in a first-class hotel where two of the victims have died. The other happened to children who were taken out for a holiday, and above eighty of them were seized with colic and vomiting soon after their meal. The question of ptomaines or microbes is quite popular. Searching inquiry is being made into both events.

Cockles are suspected of spreading typhoid. They are collected from sources similar to those which have been shown to be dangerous in the case of oysters, and are often eaten raw. Even when they are cooked the process is a very partial one.

The Hospital Sunday fund has again succeeded. At a meeting on Wednesday a distribution of £50,500 to one hundred and thirty-eight hospitals and fifty-four dispensaries was sanctioned. Since the fund started twenty-six years ago, more than a million sterling has been raised.

The Physiological Society has entertained at a dinner the two physiologists recently decorated by the Queen—Burdon Sanderson and Michael Foster.

Sir Joseph Fayrer's honors and decorations seemed full. There has now been added to them a "good service pension," which he well deserves.

---

LONDON, August 4, 1899.

PORTSMOUTH has supplanted the metropolis as the scene of medical interest during this week. A number of members of the British Medical Association left London on Monday afternoon for the annual week's meeting. Some indeed hurried off on Saturday. Others again delayed until Tuesday and a few merely took a day ticket to turn up in the section in which they were interested. A number are returning this afternoon, though many remain for to-morrow's excursions.

I gather that the meeting has been a successful one. Your own reporters furnish you with full details of the most important sectional work. It was known here that Sir T. Grainger Stewart would not be well enough to attend, and great regret and sympathy were naturally expressed at the meeting. Dr. Ward Cousins seems to have had quite a triumph, and some of his prominent fellow-citizens said he excelled himself and showed himself an orator of unexpected power. The members who had heard him on former occasions were by no means surprised to find him a good speaker.

The service at Portsea parish church was only fairly well attended, the attractions of the locality being too strong, *e.g.*, visits to the Dockyard, the *Victory*, the Gun-wharf, the Military Station Hospital, the Royal Portsmouth Hospital, and other institutions. The bishop took for his text, "Freely ye have received; freely give," which he said "embodied the foremost thought that such a body as the medical profession suggested."

For the benefit of Roman Catholic members high mass was celebrated at St. John's. This was the first occasion of a double service, and excited remarks on the question of sectarianism in a medical society. At each service there was a collection on behalf of the Royal Medical Benevolent Fund.

Wednesday opened with the temperance breakfast, at which the Bishop of Southampton made an earnest speech, especially referring to the evils of the drink habit in the middle and lower middle classes. In the evening of the same day there was a crowded meeting at Southsea under the auspices of the National Temperance League. In the afternoon the mayor's garden party was held in the asylum grounds, and was generally considered a great success. In the evening again a soirée was given by the president on the Pier. This looks like a day of festivities, but there was also a good deal of work done in the sections, and the address in surgery was delivered by Professor Ogston, who subjected the management of the army and navy medical services to a most searching criticism. He maintained that while the calls of modern science had been taken to heart in the medical services of foreign armies, they had fallen on unheeding ears among those responsible for the efficiency of our own, and this was the more astonishing on account of the contrast between the medical and other departments.

People who know Dr. George Wilson, medical officer of health of the Mid-Warwick district, expected something out of the common when they found he was to preside over the State Medicine Section. They were not surprised, but others thought his address was a gigantic joke. He pooh-poohed bacteriology, serum therapy, and other modern methods, laughed at "the insane hunt after the tubercle bacillus as if it could be bottled up in a twopenny halfpenny spittoon," and aired other heterodox notions. As there is no discussion on the addresses, he was as safe from reply as a parson in his pulpit.

Next year's meeting is to be at Ipswich, and Dr. Elliston was appointed president-elect.

The expedition for the study of malaria left Liverpool for Sierra Leone on Saturday. Major Ross is the leader. He was accompanied by Dr. Annett, bacteriologist of the Liverpool School of Tropical Diseases, and Mr. E. E. Austin, the entomologist of the British Museum. At Sierra Leone they will be joined by Dr. Van Neck on behalf of the Belgian government and the Congo Free State. Major Ross expects to be absent about two and one-half months, and will probably make Free Town the centre of his operations. The organizing of this expedition—the first scientific one for examining the subject of malaria in its home—is a great credit to the newly established Liverpool School of Tropical Diseases. We may certainly anticipate important results.

Lord Rosebery paid a tribute to the profession in his address to the students of Epsom College. He had impressed on them in various ways the value of the quality of manhood which so distinguishes the race; then considering the close association of that college with the profession and the probability that some of them would qualify for its practice, he said that profession "contains the most supreme elements of manhood of all professions; it needs tenderness and courage in the highest degree." Having dwelt on these, he added, "The profession of the physician is one long struggle in which, like the Englishman, he must never know when he is beaten until victory has gone against him."

**Acute Delirium** may result from a too free use of salicylate of sodium (℥ iii. in thirty-six hours).—*La Presse Médicale.*

# Medical Items.

**Contagious Diseases—Weekly Statement.**—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending August 12, 1899:

| | Cases. | Deaths. |
|---|---|---|
| Tuberculosis | 188 | 169 |
| Typhoid fever | 29 | 12 |
| Scarlet fever | 45 | 2 |
| Measles | 4 | 11 |
| Diphtheria | 104 | 30 |
| Laryngeal diphtheria (croup) | 0 | 1 |
| Cerebro-spinal meningitis | 0 | 6 |
| Chicken-pox | 3 | 0 |
| Smallpox | 1 | 0 |

**Trouble from Carbolic Acid.**—A man from Norwich, N. Y., who after a tiff with his wife smeared carbolic acid upon his whiskers and feigned suicide, has repented. His employer administered mustard, and the doctors poured emetic after emetic down his throat against the joker's decided protestations, and finally the stomach-tube was resorted to. When the victim stopped his struggling, the doctors found time to look into the throat and found that no poison had been taken. Moral: Don't sham suicide.

**Points in Favor of the Use of Alcohol and Their Refutation.**—Dr. Bienfait (*Gaz. hebd. de Méd. et de Chir.*, April 13th) examined point by point the various objections to total abstinence: (1) Is alcohol a digestive? No; its ingestion produces a passing excitation, interrupts the proper action of the muscles of the stomach because alcohol acts as an anæsthetic after having irritated the walls of the stomach, and it drives the blood to the skin and so hinders the action of the gastric juice. (2) Is alcohol an appetizer? No; it produces an excitation of the stomach which causes a sensation taken for hunger. (3) Is alcohol a food? No; it does not correspond to the definition of a food, and the heat that it seems to produce does not serve as an actual warmth. (4) Is alcohol heating? No; it causes a flow of blood to the skin and a lowering of temperature. (5) Is alcohol a stimulant? In no case, either physical or intellectual. (6) Is alcohol a protector against contagion? No; it predisposes the body to contagion. (7) Can we live without alcohol? This idea that we cannot live without alcohol is a prejudice that numerous facts contradict. (8) Is alcohol good for children? It should never be given to children. (9) Does alcohol increase longevity? According to reliable statistics alcohol diminishes longevity.

**Etiquette and Clothes.**—A little incident has occurred in Ireland which shows the trend of public opinion in the matter of adapting our clothes to the weather prevailing rather than blindly following any preconceived notions of supposed professional etiquette. One of the most popular barristers of the Irish bar has shocked the lord chief justice of Ireland by appearing in court with a white waistcoat on. For this "outrage" he has been publicly reprimanded by the judge; but the sympathy of the bar is with Mr. Macdermott, Q.C., and much indignation is expressed that so trivial an offence should have been noticed at all. We think that man should be allowed to follow the steps of the gentler sex and emancipate himself from the ridiculously heavy clothing he is compelled to wear in the performance of his daily work. It is quite correct nowadays for ladies to appear either in the home or the street in the comfortable blouse or skirt of light material, but the man must don the frock coat and the cloth trousers, when, under the almost tropical heat we have lately experienced, he would give anything for it to be correct for him to put on the "white ducks," or clothes of similar material. What makes for comfort makes for health, and it wants only a few bold spirits to insist on wearing a truly "rational" suit at such times, and the change might soon be effected.—*Sanitary Record.*

**Nature and Definition of Puerperal Fever.**—In the *Centralblatt für Gynäkologie*, 1899, No. 1, Olshausen calls attention to the necessity for a rational definition of "puerperal fever," and of a clear understanding of the difference between infection and intoxication. By infection he understands the presence and circulation of bacteria in the organs and fluids of circulation in the patient's body. By intoxication is meant the absorption from the birth canal of the products of bacteria contained therein. While it is almost impossible to draw a sharp distinction in the matter, still it is important to understand as clearly as possible the two conditions. He also draws attention to some infections which may enter the body through the birth canal and which do not strictly come under the term "puerperal fever." Such are tetanus, scarlatina, and diphtheria. As regards gonorrhœa, its close resemblance to sepsis brings it on the border-line of this condition. It is, however, essentially different from sepsis. It is contended by Olshausen that the term "puerperal fever" shall be applied only to those diseases caused by septic microorganisms.—*English Public Health.*

**Compulsory Notification in Great Britain.**—Prof. Sims Woodhead, speaking in regard to the prevention of phthisis spreading from human patients, says: "I must frankly confess that I am greatly in favor of compulsory notification; and I am in favor of this because I think it is one of the means of impressing upon the public, and even in some cases upon ourselves, the fact that there is danger of the spread of infection from tuberculous patients, unless proper precautions be taken by the patient and his friends to destroy all excreta and secreta that may contain tubercle bacilli. The very fact that we consider it necessary to speak of tuberculosis as a notifiable disease should render our task of disinfecting a patient and his surroundings a much easier one."—*Edinburgh Medical Journal.*

**Health Reports.**—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended August 12, 1899:

SMALLPOX—UNITED STATES.

### THE REPORT OF A CASE TREATED WITH YELLOW-FEVER SERUM.

BY ALVAH H. DOTY, M.D.,

HEALTH OFFICER, PORT OF NEW YORK.

ON Thursday, July 6th, the United States transport *McClellan* arrived at this port from Santiago, Cuba, having on board two cases of yellow fever, one a daughter of the late Dr. Clendenin, surgeon U. S. A., who recently died of this disease at Santiago, and the other Oscar F. Lackey, twenty-five years of age, a civil engineer in the employ of the Federal government. Both patients were transferred to the hospital at Swinburne Island. Miss Clendenin required but little treatment, as her symptoms were of a mild character. Mr. Lackey, however, presented a typical case of yellow fever. The report of Dr. Porter, of the *McClellan*, showed that Mr. Lackey had had a chill late on the preceeding Monday evening (July 3d), or early Tuesday morning, followed by considerable headache, pains in loins, etc. On July 5th, his temperature reached 104° F., and a large amount of albumin was found in his urine. The patients arrived at Swinburne Island about 6 P.M., July 6th, and at 7:20 P.M. Mr. Lackey's condition was as follows: Temperature, 103.8° F.; pulse, 55; respiration, 28. He suffered from headache and was very nervous, associated at times with some delirium; hemorrhage from the gums, more or less irritability of the stomach and some looseness of the bowels were noticeable. The urine contained about thirty-five to forty per cent. of albumin in bulk, and had specific gravity of 1.025 and a pronounced acid reaction. As the case under consideration was well marked and had not progressed too far, I decided to make use of the yellow-fever serum. To this Mr. Lackey's consent was readily obtained, and preparations were carefully made for its introduction. But little literature referable to the administration of the serum exists. In Sanarelli's article it is stated that the serum may be given either subcutaneously or intravenously, and that the latter method is more rapid and effective in its action. This investigator recommends that about 100 c.c. be used, partly in the veins and partly under the skin.

The serum used in Mr. Lackey's case was produced in the laboratory of this department under the supervision of Dr. Charles B. Fitzpatrick. Of this 10 c.c., when injected into a guinea-pig ten hours before inoculation with a fatal dose of a living culture of the bacillus icteroides (Sanarelli), prevented death. However, to cure guinea-pigs inoculated with a fatal dose of the living culture, a larger dose (14 c.c.) was required.[1]

Inasmuch as Mr. Lackey was the first case to be treated with the serum at this station, it was decided to use the subcutaneous method. Accordingly at 11:30 P.M. (July 6th), the first injection, consisting of 25 c.c., was given in the loose cellular tissue on the right side, just above the pelvis; at 2:30 A.M. (July 7th), three hours afterward, a second injection of 25 c.c. was administered at the corresponding place on the left side, and at 7:20 A.M. (five hours later) a final injection of 50 c.c. was made; the latter was introduced in the vicinity of the first injection on the right side. The syringe used was similar to those employed in introducing the diphtheria antitoxin, having a capacity of 25 c.c. This was carefully sterilized by boiling. The skin at the site of the puncture was treated with an antiseptic solution, and after the withdrawal of the needle, collodion was immediately applied. The operation caused no inconvenience to the patient, and no unpleasant signs or symptoms either local or constitutional followed the use of the serum.

The following table shows the temperature, pulse, and respiration preceding the first injection and for twelve hours afterward:

| Date. | Time. | Temperature. | Pulse. | Respiration. | |
|---|---|---|---|---|---|
| July 6th | 11:20 P.M. | 103.2° F. | 51 | 32 | |
| | 11:50 P.M. | 102.8 | 49 | 32 | (11:30 P.M. serum.) |
| July 7th | 12:50 A.M. | 103.0 | 55 | 28 | |
| | 1:50 A.M. | 102.4 | 55 | 27 | |
| | 2:20 A.M. | 102.2 | 53 | 28 | (2.30 A.M. serum ) |
| | 4:05 A.M. | 102.8 | 53 | 28 | |
| | 5:45 A.M. | 102.8 | 51 | 24 | |
| | 7:15 A.M. | 102.4 | .. | .. | (7:20 A.M. serum.) |
| | 8:20 A.M. | 102.4 | 54 | 24 | |
| | 10:20 A.M. | 102.1 | 51 | 26 | |
| | 12:20 P.M. | 102.6 | 51 | 24 | |

At 11:30 A.M. on July 7th, the following entry was made by the nurse on duty: "Patient brighter, headache disappeared."

It will be seen by the chart, that eight ounces of urine are recorded on the 6th of July. This covers a period of twelve hours or more—some passed in the morning before the removal of the patient to Swinburne Island was not measured by the surgeon of the vessel. On the 7th, fifteen ounces are recorded; this represents the urine passed during twenty-four hours with the exception of a small amount voided during a movement of the bowels. The amount of albumin in the urine, thirty-five to forty per cent., continued until July 12th, when it rapidly decreased and disappeared on July 15th. The specific gravity of the urine, which at first was 1.025, gradually diminished. The urine was distinctly acid and contained numerous epithelial casts.

Nervous system: But little is to be recorded under this heading, as after July 7th the patient was in a comfortable condition, mind perfectly clear and no apparent restlessness. The hemorrhage from the gums caused the patient some annoyance during the night, as rather frequent expectoration was necessary. Otherwise there were no nervous manifestation and no complaint from the patient, whose intelligence and co-operation made the care of his case a pleasant and easy task for all.

Alimentary tract: Considerable irritability of the stomach existed, and some slight vomiting occurred during the 6th, 7th, and 8th of July. After this there

[1] The details of these experiments are given in Dr. Fitzpatrick's article published in the MEDICAL RECORD, July 1, 1899.

was but little trouble in this direction. The vomited matter was small in quantity, and contained mucus, etc., occasionally having a yellow tinge. The looseness of the bowels, which was apparent for two or three days after reaching the hospital, was evidently due to the administration of a brisk cathartic while on shipboard.

Treatment.—Besides the serum, no medicinal agents (excepting whiskey) of any kind were employed in Mr. Lackey's case during the course of the disease. During convalescence a tonic containing strychnine was given.

From ten to twelve ounces of warm salt water was occasionally introduced into the rectum to assist the function of the kidneys. This was retained and evidently had the desired effect.

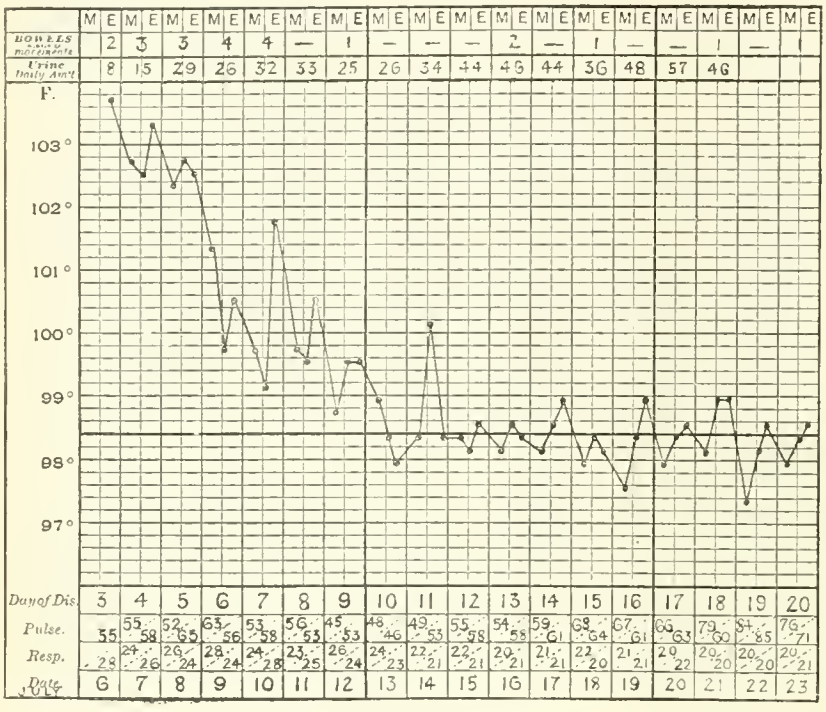

Chart Showing Temperature, Pulse, etc.

There are few diseases in which the organic degeneration is so pronounced and rapid as in yellow fever, and therefore there is no condition in which judicious nourishment and stimulation are more imperatively called for. They are, however, usually given too late to be of the greatest value. To begin the use of stimulants early in the disease is to offer prompt support to the heart before it has become too exhausted to respond. The rapid depression and degeneration which occur in yellow fever certainly cannot be fully understood by those who advocate the use of stimulants only after the third or fourth day of the disease. Nor does the value of the rectum as a means of introducing nourishment and stimulants seem to be generally appreciated. The use of the serum, if fully active, would not by any means do away with the necessity for giving careful attention to the nourishment and stimulation of the patient. Marked degenerative changes have usually taken place before this agent can be administered. The therapeutic action of the serum does not repair the tissue or take the place of nourishment, and at most it only counteracts the infection due to the specific organism and in this manner diminishes the mortality from of the disease.

In Mr. Lackey's case, during the first three or four days, fresh milk peptonized at the hospital was given in amounts ranging from a tablespoonful to two ounces every two hours. A teaspoonful of whiskey was occasionally added. This was suspended when the stomach exhibited signs of irritation. During this period, however (three or four days), six ounces of peptonized milk with from one-half to one ounce of whiskey was given by the rectum three times during each twenty-four hours. After the fourth day at the hospital the nourishment was rapidly increased. In addition small quantities of one of the bottled waters (still) were frequently given. Champagne and sparkling waters were not well borne by the stomach.

I am well aware that the value of the serum in the treatment of yellow fever cannot be definitely decided, until it has been employed in the treatment of a large number of cases. Therefore in this instance it is consistent only to present the facts in connection with the case.

Mr. Lackey recovered from the disease; whereas cases of yellow fever brought to this station on incoming vessels, unless they are of a mild character, usually terminate fatally. The care and treatment of yellow fever on shipboard are necessarily restricted and unsatisfactory, and when to this are added the climatic changes, which take place between Cuba and this port, and the exhaustion incident to the transfer of the patient from the vessel to the hospital at Swinburne Island, the prognosis is very unfavorable.

The nervous symptoms which were apparent in Mr. Lackey's case practically terminated on July 7th, and did not return. The record of the pulse shows no evidence of heart failure, or any other unfavorable signs. A reference to the charts will show that the amount of urine passed after July 6th was rather large, considering the fact that the kidneys were seriously affected, as shown by the amount of albumin present. The favorable conditions and result which I have just enumerated are what might be expected to follow the successful use of the serum, which is believed to limit the destructive action of the specific organism in the system. However, the age of the patient, an apparently good constitution, the early administration of nourishment and stimulants, with the use of saline solution by the rectum, and the most careful watching and nursing, may have contributed largely to the satisfactory termination of the case.

The importance of a thorough investigation as to the value of the serum treatment in yellow fever cannot be overestimated. The good results already obtained in diphtheria justify the belief that this method of treatment will sooner or later prove to be of great value in yellow fever.

The work already begun by this department in the direction above referred to will be continued until a definite conclusion is reached. The serum is now being tested in Vera Cruz and some has been sent to Brazil and other sections where yellow fever is almost always present and where ample opportunity can be given for a thorough test. Additional horses are now being inoculated, in order that there shall be no delay in the experimental work. This is the only scientific method of determining the value of serum.

**Chorea.**—Oil of wintergreen combined with its own weight of vaseline, rubbed over painful joints lessens the pain and benefits the chorea.—Luigi.

# BRIGHT'S DISEASE, OR NEPHRITIS.

By WALTER SANDS MILLS, M.D.,

NEW YORK CITY.

**Historical Note.**—In 1827, Richard Bright,[1] one of the attending physicians to Guy's Hospital, London, first called attention to the association of albuminous urine, dropsy, and diseased kidneys. This report is one of the most interesting monographs in medical literature. His description of the clinical symptoms observed and of the macroscopic appearances of the kidneys found after death will forever remain a classic. Bright reported a number of cases of dropsy with death. Post-mortem examination of some of the bodies showed diseased kidneys. In studying the clinical histories in conjunction with the lesions found on the autopsy table, Bright discovered that when the urine of dropsical patients had been coagulable by heat, there were found at the necropsy extended pathological changes in the kidneys; whereas, on the other hand, when the urine of dropsical patients had not been coagulable by heat, the kidneys, as a rule, were found to be healthy. He summed up these observations in the following words: "I have never yet examined the body of a patient dying with dropsy attended with coagulable urine, in whom some obvious derangement was not discovered in the kidneys."

Heretofore, dropsy had been recognized as due to impeded circulation, either from disease of the heart or of the liver, or as due to the mechanical interference of tumors. Bright's observations led him to believe that dropsy might also be due to impeded circulation from disease of the kidneys; for in many of his cases the heart and liver were but little, if at all, diseased, and the kidneys only were at fault. Nevertheless, he did not overlook the fact that hypertrophy of the heart seemed sometimes to be associated with degenerated kidneys. In some of his cases Bright also noted variations in the amount of albumin in the urine from day to day; in other cases he found albuminous urine and degenerated kidneys, but no dropsy.

The publication of his series of cases by Bright directed special attention to the study of diseased kidneys, and his name was, by common consent, given to the disease first described by him.

**Definition.**—Bright's disease has been variously defined, nearly every author giving a definition of his own. The definition that, in a few words, seems to me best to describe the conditions found, is,[2] "A disease characterized by degeneration of kidneys whereby the excretory function is so impaired that urea is not sufficiently eliminated by the blood: any disease of the kidneys marked by the persistent presence of albumin in the urine and attended by disintegration and wasting of the organ."

**Theories as to Its Origin.**—It will be well to stop for a moment to consider theories as to the origin of Bright's disease. Bright himself ventured the following proposition: "It is probable that the altered action of the kidneys is the result of the various hurtful causes influencing it through the medium of the stomach and the skin, thus deranging the healthy balance of the circulation, or producing a decidedly inflammatory state of the kidney itself." In other words, he considered the changes in the kidneys to be the result and not the cause of disease.

The disease is general with specially marked degenerative changes in the kidneys. Dickinson,[3] Millard,[4] and others consider the changes in the kidneys to precede the appearance of albumin in the urine and deterioration of the blood. On the other hand, Semmola,[5] for more than thirty years, has maintained the contrary. By experiment, and deduction therefrom, he concludes that the blood always first becomes deteriorated so as to contain an increased amount of albumin. This deteriorated blood may be due to direct poisoning, as in the acute infectious diseases, or in the ingestion of certain drugs. Otherwise, Semmola believes the deterioration to be due to interference with the respiratory function of the skin, thus causing the retention in the blood of noxious substances that would else be eliminated.

To me Semmola's views seem to be the correct ones. His experiments certainly are convincing. In one series he varnished half the bodies of several dogs: in a few days albumin appeared in the urine, subsequently followed by pathological changes in the kidneys.

Bradford[6] has been unable to find any direct relationship between the blood-vessels of the kidneys and of the skin. It can be seen, however, that when the respiration of the skin is inhibited the excrementitious matters thus kept in the blood are perforce required to circulate through the kidneys. It is this impure blood which causes the pathological changes in the kidneys in Bright's disease.

**Classification.**—As the changes that take place in the kidneys in Bright's disease have become better understood they have been found to be due to a true inflammation. Therefore the word nephritis has come to be applied to it. Different observers have made different classifications of nephritis. From a clinical standpoint the best classification is Flint's[7] division of the disease into acute nephritis and chronic nephritis. Strümpell[8] describes: (1) acute nephritis, (2) subchronic and chronic forms of nephritis, with the exception of the genuine contracted kidney, (3) contracted kidney. This is the classification most generally followed. Although typical cases of this so-called subchronic nephritis and of the contracted kidney differ in essential particulars, yet frequently it is clinically impossible to distinguish them. Moreover, the treatment of Bright's disease is mainly symptomatic, and as the same symptoms may be present in all its forms the same methods of treatment may hold good in all its forms.

From the pathological point of view again there is the acute and the chronic nephritis, but with many and varying anatomical divisions according to the part of the organ mainly affected. Bright described three forms of diseased kidney: (1) The organ loses firmness, it looks yellow and mottled. The kidney may be slightly or much enlarged. (2) The surface is granulated as though it had been sprinkled with grains of sand. The interstitial tissue is affected: it is opaque, white, and occasionally no anasarca accompanies it. (3) A contracted kidney with less interstitial inflammation. Later in his report he said it was impossible that each of these forms was merely a different stage of the same progressive degeneration.

This idea, that varying forms of kidney found in Bright's disease were merely stages of one disease, has been advocated by some of the later students of the subject, notably by Frerichs,[9] who divides nephritis into, (1) the stage of hyperæmia and commencing exudation; (2) the stage of exudation and commencing change of the exudation, and (3) the stage of degeneration and atrophy. From this simple classification there are numerous others varying all the way to Councilman's[10] fourteen anatomical divisions of parenchymatous nephritis alone. Delafield and Prudden[11] include congested kidneys under the generic term Bright's disease. This is a mistake, as, although albumin and dropsy may occur, the dropsy at least is usually due to other causes, and the kidneys after death show none of the changes recorded by Bright.

A careful review of much of the literature of Bright's disease, together with a close study of clinical cases and an opportunity for post-mortem work, suggest to

me the desirability of dividing the subject into acute Bright's disease and chronic Bright's disease.

**Acute Bright's Disease.**—Roughly speaking, the kidney is composed of the parenchyma or secreting portion, and of the connective or interstitial tissue. The entire organ is richly endowed with blood-vessels. It is subject to all the changes of inflammation from simple congestion to exudation and degeneration of plastic material. In some diseased kidneys the principal damage done seems to be in the parenchyma of the organ; in others the greatest change is in the interstitial tissue. Bright's disease has therefore been divided into parenchymatous and interstitial nephritis. Anatomically, this is convenient. It must be borne in mind, however, that all subjects of Bright's disease present kidneys that are more or less damaged in every part. The terms parenchymatous and interstitial are merely relative. Clinically, it is often impossible to differentiate between these forms.

Morbid anatomy—acute parenchymatous nephritis: Acute parenchymatous nephritis has been variously called acute tubular nephritis, acute glomerular nephritis (Klebs), acute diffuse nephritis, acute croupous nephritis (Millard), acute degeneration of the kidneys (Delafield and Prudden).

On post-mortem examination the kidney is usually found to be enlarged. The increase in size may be slight, or it may be so great as, in a case reported by Dickinson, to burst the capsule. The whole organ may be enlarged, but the principal increase is in the cortex. The capsule is non-adherent. The surface is smooth and hyperæmic.

On section the cut surface exudes blood. The kidney substance is hyperæmic. The Malpighian bodies are injected and show in the cortex as minute red spots. The cones are decidedly reddened, in some cases purple in color. The pelvis of the kidney also shows a heightened color. In fact, the whole organ may be so congested as to be almost of a chocolate hue. There is a fine illustration of this form of kidney in Bright's original memoir. Other kidneys are paler than those above described. On washing the cut surface the distended tubules, containing exuded fibrin, fatty and destroyed epithelium, and so on, show themselves as yellowish streaks, thus giving the washed section more or less of a buff color.

Congestion and then inflammation take place. There is cloudy swelling of the epithelium lining the tubules. This has a tendency to become loosened and to fall off into the tubes. After the epithelium has become impaired there is an exudation of serous fluid, leucocytes, and red corpuscles into the tubes, and to a slight extent into the interstitial tissue. The tubules are now filled with a mass of epithelium, granular matter, leucocytes, red corpuscles, and fibrin, so great as often to obliterate the channels. This diminishes the secretion of urine. It is the mass of débris which, as before stated, gives the gross appearance of a pale infiltration. Fatty degeneration, according to Coats,[12] appears in portions of the epithelium. Casts are found in the convoluted and straight tubules and in the loops of Henle. Sometimes fibrin is found next the basement membrane. It probably gets there through the tubules. This is said by some observers to seal the tubules and thus to cause a diminution of urine.

In more protracted cases and in scarlatinal nephritis the interstitial tissue becomes involved. Dickinson says that when this point is reached the process is at the dividing line between the acute and the chronic forms.

Acute interstitial nephritis: Councilman[13] has very recently described what he calls an acute interstitial nephritis. He defines it as "an acute inflammation of the kidney characterized by cellular and fluid exudation in the interstitial tissue, accompanied by, but not dependent on, degeneration of the epithelium; the exudate is not purulent in character, and the lesion may be both diffuse and focal." It accompanies or follows the infectious diseases, as scarlet fever, diphtheria, and so on. Councilman believes it to be the most common form of kidney found in the infectious diseases of children. It is also found in some of the other infections. This, together with its focal character, leads Councilman to consider the disease to be bacterial in origin, although as yet he has been unable to demonstrate that as a fact. It is only fair to other observers to state that many of them have noted the great interstitial changes in nephritis following the acute infections, especially scarlet fever.

To the eye, Councilman's acute interstitial kidney shows an enlarged organ. It may be very much enlarged, or it may be slightly so or not at all. The capsule is thin and easily removed. The kidney is pale, grayish, and mottled. In some cases the surface is irregular. On section there is found to be an increase in size of the cortex. The glomeruli are not injected but have a grayish appearance. The kidneys are soft, lax, and friable. They exude a milky fluid, possibly degenerated epithelium. Councilman says it is not pus. Occasionally the macroscopic changes may be slight.

Under the microscope there is found to be an intense cell infiltration of the interstitial tissue. This is both general and local. It is most marked just beneath the capsule and at the base of the pyramids. These cells are packed in the middle of the cortex and around the glomeruli. They resemble the plasma cells of Unna. The tubular epithelium may be destroyed, or its change may be slight. The blood-vessels are always changed, and the plasma-like cells found in them.

Pathology: There are three symptoms associated with all forms of Bright's disease, the pathology of which will be considered at this point. They occur in both the acute and the chronic forms of nephritis. I refer to the appearance of albumin in the urine, dropsy, and uræmia. It is this trio of associated symptoms that individualizes Bright's disease. It is this trio of associated symptoms that, found in every form of the disease, frequently makes clinical differentiation of the varying pathological forms of kidney impossible. As a rule, all three symptoms appear at some time during the history of each case. Many exceptions, where one or another of these symptoms was absent, have been reported. Of the three albumin in the urine is the most frequently found. Occasionally a case will run its course without the detection of albumin. When this happens I believe that it has been overlooked, either by too infrequent examination of the urinary secretion, or by faulty methods of analysis. Cases of Bright's disease in which albumin is actually never present in the urine I believe to be extremely rare. It may be absent for a time, but not during the entire course of the disease.

The albumin found in the urine of nephritis is from the blood. Under normal conditions this is not found in the kidney secretion. The cause of its appearance is still a mooted question. Cohnheim's theory is the generally accepted one. He claims that it is due to change in the epithelium of the glomeruli, thus allowing the albumin to pass through. According to Semmola (*vide supra*), this change in the renal epithelium is produced by the deteriorated blood. That change in the glomerular epithelium alone allows of the passage of albumin is corroborated by the fact that in chronic interstitial nephritis, when the glomeruli are largely destroyed, albumin is scant and sometimes absent.

Dropsy is the next most constant symptom of Bright's disease. It is nearly always found in the

acute form, and is found in the majority of cases of the chronic disease. It may not be evident for a long time in some of the latter, but if carefully searched for it will usually be found to a varying degree, especially toward the end, in nearly every case. Dropsy consists of an infiltration into the tissues and serous cavities of a watery fluid. This dropsical fluid is pale or colorless, of low specific gravity—1.006 to 1.012—and composed of water, salts, and extractives. It contains albumin. The fluid comes from the blood. Cohnheim's theory, that dropsy is due to changes in the walls of the blood-vessels, is to-day generally accepted. Renal dropsy, according to Lazarus-Barlow,[14] exhibits itself first in the loose subcutaneous tissue. He claims this to be a proof of Cohnheim's theory. Dropsy due to defective heart's action is found in dependent portions of the body. So is dropsy due to obstructed circulation. If the heart recovers its tone or if the obstruction is removed, the dropsy promptly disappears. Further than the above the pathology of dropsy is not understood.

The third of the trio of symptoms is uræmia. This is found in any form of the disease, but is most often associated with chronic interstitial nephritis. The pathology of uræmia is obscure. The most recent experimental work in pathology of the kidneys with which I am familiar is that of Bradford.[6] In the Goulstonian lectures delivered before the Royal College of Physicians in March, 1898, Dr. Bradford devoted some attention to the subject of uræmia. In conclusion Bradford asks: "Is uræmia due to a retention of some body or is it due to the formation of something? Experiment and clinical evidence is against the retention theory. The only uræmia of the laboratory is the latent uræmia of the clinic. It is probably due to some abnormal product of disordered metabolism." In summing up he says, "(1) Uræmia is not due to sudden retention. (2) In kidney disease and after experiment there is evidence of great tissue disintegration; and it is probable that uræmia depends on this."

That uræmia acts as a powerful poison to the nervous system is well known. It exhibits itself as headache, drowsiness, stupor, coma, convulsions, reflex nausea, and vomiting. Before an outbreak of uræmia there is a diminution in the amount of urea excreted by the kidneys. There is an increase in the percentage of urea in the blood. These few facts comprise the sum total of our knowledge of the pathology of uræmia.

Exciting causes: The most frequent direct exciting cause of acute Bright's disease is scarlet fever. The specific poison probably acts directly on the kidneys. Smith[15] reports an acute nephritis in a nurse who had cared for a case of scarlatina, but who at no time presented any other of the effects of the specific poison. Flint also reports that he has seen acute nephritis occur in several attendants on scarlet-fever patients. He says that most of these patients had had scarlet fever years before. Scarlatinal nephritis may develop at any stage of the original disease. It is most apt to come on toward the close of the third week. It may come on as late as a month after convalescence is established. Smith says nephritis occurs most often in mild cases, and usually follows exposure to cold. This tendency of scarlet fever to produce Bright's disease makes it imperative on the attendants that all possible exposure of the patient be guarded against. Even then it may develop in the most carefully cared-for patient.

Acute Bright's disease may occasionally follow the other infectious diseases, as diphtheria, pneumonia, typhoid fever, typhus fever, relapsing fever, smallpox, measles, erysipelas, cholera, dysentery, and so on. Malaria occasionally produces acute Bright's, but is more apt to cause the chronic form.

Exposure to cold associated with dampness is a frequent cause of the acute nephritis. Cold alone is not so bad. Bright's disease is not a disease of cold countries.

Alcohol has long been considered to be a potent cause of acute nephritis. It is more probably due to the carelessness of alcoholic habitués in exposing themselves, and to their well-known lessened ability to react against malign influences, than to the alcohol itself.

Pregnancy is another cause of acute nephritis. It occurs more often in primiparæ. It is most apt to develop toward the end of gestation.

Certain poisons, if ingested in sufficient quantity, will cause acute nephritis. The most common ones are arsenic, cantharides, carbolic acid, chlorate of potash, turpentine, and some of the mineral poisons. Millard reports a case caused by essence of ginger that had been taken to cure dyspepsia.

Extensive burns are very apt to cause acute Bright's disease. Certain skin diseases are also said to be responsible for a few cases.

Symptoms: Acute Bright's disease is a self-limited disease running a course of two weeks to two months, and ending in recovery, chronic nephritis, or death. The onset is usually sudden. It may be ushered in by a chill or chills, accompanied in some instances by a slight rise in temperature, which rarely goes beyond 103° F. Children are more subject to increased temperature than are adults. The skin is dry. This last is characteristic. There is loss of appetite, possibly with nausea and vomiting. The respiration is quickened. Pain in the loins in the region of the kidneys is often present, especially on deep pressure. The pulse rate is increased. Sometimes there is hypertrophy of the heart, but this is not common. A more frequent symptom is rapid dilatation. The percentage of urea in the blood is increased. Anæmia develops early. This, with the œdema, gives the patient a peculiar waxy look. Epistaxis is quite common. Purpura may appear.

In the vast majority of cases the first symptom noted is a sudden appearance of œdema in one or more parts of the body; usually it is a general dropsy or anasarca. This is one of the earliest and most frequent symptoms of the acute disease; it is rarely absent. After exposure to cold anasarca may set in within twenty-four hours. It usually shows itself first in the loose areolar tissue about the orbit. It may show itself first about the ankles. As a rule, however, it develops suddenly and is general. Nearly always it is a marked symptom: it may even be so great as to break the skin. Quite often it will exhibit itself as œdema of the lungs. If there is any reason to suspect acute nephritis, œdema must be most carefully searched for, otherwise it may be overlooked. I have seen two such cases. Both patients were emaciated. In one œdema was not suspected. At the necropsy I found several quarts of fluid in the abdomen. The other case showed a slight puffiness about the eyes, but ascites was said to be absent. On most careful examination I was able to demonstrate it. My diagnosis was later confirmed at the necropsy. Favorite places for the œdema to develop are in the loose areolar tissue about the eyes, about the genitals, about the ankles and legs, in the abdomen, and in the lungs. Œdema and diminished urine are said to hold a reverse relation to each other; as one increases the other diminishes. That is, when the dropsy is greatest the amount of urine passed is the least. When the dropsy begins to disappear, the quantity of urine increases.

In acute nephritis the urine may be entirely suppressed. As a rule it is much diminished, of high color, and with increased specific gravity. Frequent micturition is a leading symptom. On examination it

is found to contain a large percentage of albumin, more, I believe, than in any other form of the disease. On very rare occasions albumin may be absent. The quantity of urea and of phosphates is diminished. The urine is clouded and deposits a heavy sediment. Under the microscope this is found to be composed of epithelium, casts, and blood. In acute Bright's epithelial and blood casts predominate; hyaline and other form are not so prevalent. Casts are composed of débris deposited and compressed in the tubules. Some authorities claim that those passed with the urine come only from the straight tubules, casts found in the convoluted tubules not being able to get through the narrower straight ones. Coats, on the other hand, says that the casts are more or less compressible and flexible, and that those formed in the convoluted tubules can accommodate themselves to the smaller diameter of the straight tubules and thus pass through. Leucocytes and red blood corpuscles are found in abundance in the sediment. In fact the heightened color of the urine is due to the quantity of blood contained.

Eye changes are rarely present in acute Bright's disease. Sometimes sudden blindness develops. This usually disappears in a few hours. No retinal changes are found to account for it. The symptom is probably of central origin and may be due to uræmic poisoning or to the pressure of fluid in the brain.

Acute Bright's disease may announce itself in the form of convulsions. This is especially true of the nephritis of pregnancy and of scarlatina. If careful watch is kept over the kidneys during gestation and during the progress of infectious diseases, this accident will not be so apt to take the attending physician unawares, for analysis will nearly always show that trouble is brewing. The convulsions of pregnancy are nearly always due to nephritis. These are known as "eclampsia." According to Lusk[6] this occurs about once in every five hundred pregnancies. Convulsions, coma, and other profound nervous disturbances are probably due to uræmia. Except as just noted, uræmia is not so common in acute as in chronic Bright's disease.

Complications: The complications of acute Bright's disease other than those enumerated in the symptomatology are not numerous. Bronchitis is nearly always present. In fact it is usually classed as a symptom. Pericarditis, pleuritis, pulmonary congestion, pneumonia, may occasionally develop.

Diagnosis: In typical cases the diagnosis is easy. The symptoms are rapid pulse, increased respiration, dry skin, œdema, frequent micturition, suppressed or diminished urine. If any urine is passed it is found to contain albumin, casts, and blood. If there is a history of convalescence from scarlet fever or other infectious disease, or of exposure, the diagnosis is certain.

Sometimes an acute exacerbation of a chronic nephritis will give the same combination of symptoms. Then, without the previous history of the case, it is impossible to distinguish it from the acute form. I have had one such case in hospital practice. A woman, aged fifty-two years, came in with a history of exposure followed by all the classical symptoms of acute Bright's. The quantity of urine passed voluntarily and by catheter varied slightly from day to day, but it averaged less than half an ounce for three weeks, when she died. At the necropsy the kidneys were found to be of the typical contracted kind. They had evidently been a long time in developing. The case was one of an acute exacerbation of a chronic condition.

Acute tuberculosis has sometimes been confounded with acute nephritis. The history of the case is of value in differentiating the two diseases. In the former there is extreme emaciation and lack of œdema. The two diseases may coexist.

Acute Bright's disease may have to be distinguished from the acute congestion of inflammatory disease. In nephritis there is abundance of albumin and of casts, in congestion only a trace. If nephritis is induced by acute inflammatory disease, it follows that disease, and symptoms of the kidney affection thereafter cease to bear any relation to it. If acute congestion of the kidneys accompanies an infectious disease, the kidney symptoms increase as the original disease grows worse, and decrease and disappear when convalescence is established.

Suppurative nephritis is differentiated from Bright's disease by the history. It originates from external violence, by metastasis from suppuration in some other part of the body, by irritation from calculi. Suppurative nephritis is usually accompanied by pain, swelling, and affects but one kidney. In Bright's disease enlargement can rarely be demonstrated and both kidneys are alike affected.

There is a transient albuminuria that is found after eating certain things, after violent or exhausting exercise, and sometimes in adolescence. Cases of this nature are classed as cases of physiological albuminuria. Millard, in the last edition of his book, denied that there was any such thing as physiological albuminuria. He claimed that he never had found albumin except in diseased kidneys. While not quite willing to deny the existence of physiological albuminuria myself, yet I believe that apparently healthy individuals whose urine occasionally contains albumin need close watching. They should once in a while be thoroughly examined for other evidences of Bright's disease.

It is well known that albuminuria is a frequent symptom in pregnancy. It may be due to congestion of the kidneys caused by pressure, it may be due to acute nephritis, it may be due to chronic nephritis. Lusk makes the statement that eclampsia is more apt to occur in patients who have developed the albumin during pregnancy than in those who were suffering from well-marked nephritis beforehand. Nevertheless, he advises against pregnancy in subjects of Bright's disease. The albumin of pregnancy appears in the later months and is associated with hyaline and granular casts. These symptoms usually disappear after labor. When the first symptom noticed is dyspnœa, the lungs will of course be examined. If œdema is present, examination of the urine will show whether or not nephritis is also present.

Convulsions or coma may first call attention to the disease. If due to uræmia, these conditions are usually preceded by a diminution of urine. Other premonitory signs are vertigo, headache, dulness of the intellect, impaired hearing, and blurred vision. There are also apt to be nausea and vomiting. When these symptoms are present, careful analysis of the urine is in order.

If the patient is seen for the first time in convulsions or in a state of coma, but without data on which to base a clinical history, the differential diagnosis is impossible. Subsequent developments will help very materially to clear up the case. If the coma lasts for any length of time, the patient must be catheterized and an analysis made of the urine. The importance of this is obvious.

Uræmic convulsions are epileptiform in character and usually pass into coma. The coma is profound and there is stertorous breathing. The temperature does not rise, the pulse is rapid, the skin is dry. In true epilepsy the convulsion is followed by a condition of stupor. If roused, the patient's mind is dazed. If not roused, the patient usually falls asleep and sleeps quietly for a time.

After cerebral hemorrhage the temperature rises and the pulse tends to go slower. Some form of paralysis is produced; this may be detected even when the patient is unconscious. The pupils are apt to be uneven. If convulsions are present, they follow and do not precede the coma.

Ordinary syncope is too transient a symptom to be confounded with uræmic coma.

In coma produced by poisoning, unless the dose is immediately fatal, the development of the symptoms is gradual. Irritant poisons disfigure the lips and fauces; this should lead to their detection. Narcotic poisons cannot always be distinguished from uræmia.

In unconsciousness from the effects of heat there is a better chance for differentiation at the beginning, because it occurs only in hot weather or in hot places. The skin is dry, the temperature is very high. If the patient is a victim of sunstroke, the pulse will be full and bounding and the face red and congested. If the case is one of heat prostration, the pulse is very weak and rapid and the face excessively pale.

In surgical unconsciousness, concussion of the brain, fracture of the skull, and shock, the testimony of the bystanders is usually available.

Prognosis: The prognosis of acute Bright's disease is usually good. The majority of cases get well. If the acute symptoms subside, the œdema disappears, the albumin becomes less, and the quantity of urine passed increases, the patient is improving. The œdema disappears long before the albumin does.

Ordinarily acute nephritis lasts from two to six weeks. If the symptoms persist for two months or more the disease is becoming chronic. This is not a common course for it to take. From one-quarter to one-third of the victims die. The patient may die in a few days in coma or convulsions, or he may live for some time and eventually die from exhaustion or from some complication, as œdema of the lungs and so on. Death may be caused by extension of the inflammation to internal organs.

Treatment: The patient ill of acute Bright's disease must be put to bed and kept there until all acute symptoms have subsided. The room must be kept warm and at an even temperature day and night. The patient must be protected from any possible danger of exposure to draughts of air or other chilling influences.

Milk is the best food. To make it more palatable it may be flavored with coffee, salt, or soda water. There are persons who will be upset by milk. Thoroughly shaking the milk before use will make it more digestible. Diluting it with lime water or carbonated water has the same effect. Some patients will take more kindly to buttermilk or to kumyss than to plain milk. Gruel may be sometimes used to advantage.

The use of tea, coffee, alcohol, and spiced foods must be stopped until after the patient is thoroughly convalescent. In exceptional cases very dilute whiskey and water may be given if the patient is excessively weak. The drinking of large quantities of pure water —several quarts daily—is essential. Lemon juice added to the water is very beneficial and may be taken *ad libitum*. Water holding in solution benzoate of sodium or citrate of potassium is used by some. My own preference is for a pure spring or distilled water with the juice of half a dozen to a dozen and a half lemons a day. This acts not only as a diuretic, flushing out the kidneys, but also has a direct effect on the kidneys, soothing the inflammation and diminishing the amount of albumin excreted.

As the acute symptoms subside and convalescence is established, meat broths, soft-boiled eggs, and fruits may be added to the bill of fare. A full diet of the character usual to the patient will have to be adopted slowly and with caution, all the time closely watching and noting the slightest changes in the urinary secretion.

The failure of the kidneys to excrete the usual quantity of urine, and the stoppage of the respiratory action of the skin as evidenced by its dryness, together cause the retention in the system of a lot of excrementitious matters that would otherwise be got rid of. To help eliminate this material as far as possible, diaphoretic treatment is resorted to The best method is the application of heat in various forms.

The patient may be wrapped in dry hot blankets and given hot drinks. This method of diaphoresis can be employed with almost every patient. A more effective way, but one that is dangerous in cases with heart lesions, is to give the patient a hot-air bath. This can be done by completely covering the patient, except the head, with blankets, in such a way as to form a sort of air chamber, and devising some apparatus to heat the air underneath. The hot-air bath ought to last no longer than twenty minutes. Care must be used lest the patient take cold: a rub-down afterward with alcohol and water will help to prevent that.

The hot pack is another method that lends itself to quite general application. This consists in wrapping the patient in a sheet wrung out in hot water and wrapped round about with blankets. This hot pack may be kept up for from a half to one hour. Finally the hot-water bath may be utilized. This may last for half an hour. In utilizing any one of the methods described above, close observation of the patient will have to be kept up to guard against exhaustion or distress of the vascular system. It is an advisable procedure to rub the patient thoroughly with dilute alcohol both before and after either the hot-air or the hot-water treatment.

Pain over the kidneys may sometimes be relieved by dry cupping. Poultices do not seem to do so well.

If the bowels are constipated and the urine is scanty, it is claimed that a good deal of the excrementitious matter may be eliminated by means of cathartics. For a mild cathartic I know nothing better than rubinat water. Senna or gamboge may be used. A more popular remedy is calomel. This may be given in eighth to quarter grain doses, repeated every hour or so.

If uræmic eclampsia or coma is impending the treatment by means of hot air or hot water, as outlined above, must be resorted to. Active depletion may be used. This is usually done by the use of pilocarpine hypodermatically, a quarter to a sixth of a grain at a dose. This relieves the dropsy as well as the uræmia. Other drugs used in this way are jalap, drop doses of elaterium, and croton oil.

Loomis[12] speaks very strongly in favor of the use of morphine hypodermatically in uræmic convulsions. He claims that it not only quiets the patient, but that it has a beneficent effect on the kidneys as well.

Inhalation of chloroform is a frequently used method for controlling uræmic convulsions. It has no curative effect, but it serves as a temporary relief until other means can be employed.

In uræmic delirium my only success has been with hyoscyamus. I have seen that put the patient to sleep. After a few hours he wakened in a normal state of mind.

In eclampsia Lusk recommends the use of veratrum viride in doses of fifteen drops of the tincture to a teaspoonful of water, repeated in a half-hour if necessary. If beneficial in eclampsia there is no reason why it should not be of service in any case of uræmic convulsions.

For the lesser manifestations of uræmia other methods are of service. In uræmic headache I used nitroglycerin in the 1:100 solution, diluted, so that my patient gets less than a drop at a dose. Bartholow[13]

and others mention its use. Belladonna is another remedy that may be called for in this condition.

For the nausea sometimes found in slight uræmia, bits of cracked ice held in the mouth frequently do much to relieve.

The œdema of nephritis will often respond promptly to treatment. My favorite drug, if œdema is general, is infusion of apocynum. Ten or fifteen drops may be given every hour. The quantity of urine passed is increased, the œdema is held in check or reduced, and the patient feels generally stronger.

For œdema of the lungs alone I use apis mellifica. Its action is prompt and certain. I have verified it many times in practice. I use a 1:100 preparation, and give half-drop doses every half-hour until relief is apparent. Another remedy that may fit the dropsical symptoms, and is good for the anæmia and debility of Bright's disease, is arsenic. I use Fowler's solution, and push it until the physiological effects are produced.

When the œdema becomes so great as to threaten to break through the skin, and medicinal and hygienic measures have no effect on it, it is necessary to resort to operative measures. The skin of the legs may be punctured under strictly antiseptic precautions, if the œdema is great there. In ascites tapping the abdominal cavity and drawing off the fluid is sometimes necessary. Or it may be necessary to tap the chest to relieve the pressure there.

Aconite in minute doses frequently repeated will be found of service in reducing the hyperæmia of acute Bright's disease.

Cantharides has a beneficent action on the kidney of acute nephritis. It is best given in drop doses of the tincture. It also seems to diminish the dropsy. Later on, when the dropsy has gone down but albumin still remains, bichloride of mercury will be found to be of service. Drop doses of a 1:10,000 solution is efficient. If the gastro-intestinal disturbances are marked, if there is much flatulence with scanty urine, turpentine in drop doses will help very much.

Cactus grandiflorus is the remedy for a lesser degree of flatulence causing palpitation of the heart.

The anæmia of acute Bright's is treated with iron and cod-liver oil. Inhalations of oxygen are also of value for this symptom; the oxygen also acts on the blood in such a way as to cause a diminution of the amount of albumin passed.

**Chronic Bright's Disease.**—As in the acute form, so in chronic nephritis, there are many names by many investigators. In describing the morbid anatomy of chronic nephritis I shall describe two forms, parenchymatous and interstitial. I must again call attention to the fact that frequently these two forms are clinically indistinguishable. There are typical cases that may be differentiated before death, but there are more that are on the border line and cannot. In all forms of chronic Bright's disease both the parenchymatous and the interstitial tissues are affected. The varying anatomical divisions merely imply that one part of the kidney structure is more damaged than is another.

Morbid anatomy: Chronic parenchymatous nephritis, otherwise known as chronic tubular nephritis, chronic diffuse nephritis, chronic diffuse nephritis with exudation (Delafield and Prudden), chronic croupous nephritis (Millard), chronic desquamative nephritis, chronic catarrhal nephritis, the large white kidney, and, later on in the disease, the small white kidney.

The kidney of chronic parenchymatous nephritis differs but little from that of the acute form. The changes are merely slower in taking place. Usually the organ will be found to be enlarged. This is called the large white kidney. It may be as much as three times its normal size. The capsule is non-adherent. The surface is smooth and pale. There may be patches of congestion. On section it is found that the increase in bulk is mainly in the cortex. The cones are less enlarged and retain their original color.

This form of kidney must not be confounded with the amyloid, lardaceous, or waxy kidney, which is also large, white, and smooth. This latter is due to a general amyloid degeneration, and is always found associated with waxy liver and waxy spleen. It is never found except after a wasting disease. An application of a watery solution of iodine simply discolors the parenchymatous kidney; with the amyloid kidney it gives a mahogany color to the waxy part and a yellowish tinge to the remainder. Amyloid degeneration may occur or coexist with any form of nephritis.

In chronic parenchymatous nephritis the secreting portion of the kidney is specially involved, the interstitial portion less so. The diseased condition is general or diffuse—that is, the tubular and the intertubular tissues are both affected. There is cloudy swelling of the epithelium, which later loosens and becomes detached. The tubules are distorted and obstructed with the débris until they look varicose. Fatty degeneration of the epithelium occurs, showing as yellowish streaks and giving the organ its light color. The packing of débris into the tubules may be so extensive as to obscure the interstitial tissue. The blod-vessels may be crushed. Blood and casts are found in the tubules. Later, as the case progresses there develops a new formation of interstitial tissue with an infiltration of leucocytes. This new connective tissue extends out to the capsule, which may become thickened. In time this may distort the organ. There are slow contraction and granulation. The shrinking of the new formation causes the cortex to sink in, and we have as a result the small white kidney, which somewhat resembles the contracted or chronic interstitial kidney. The latter, however, begins its change at the surface, whereas the parenchymatous form begins its change in the interior. Even when firmly contracted the small white kidney is smooth, although it may have an irregular surface. It is soft and flabby and the capsule is non-adherent. The cortex may become thin and the glomeruli sclerosed. The organ retains its original buff color. Much of the cortical excess in the deeper parts remains.

Chronic interstitial nephritis: Chronic diffuse nephritis without exudation (Delafield and Prudden), contracted kidney, granular kidney, granular atrophy of the kidney, cirrhosis of the kidney, renal sclerosis, gouty kidney; these are some of the names given to inflammation of the connective tissue of the kidneys. It must not be forgotten that the parenchyma of the organ is also involved.

This form of kidney is generally recognized as chronic from the beginning. It is usually much reduced in size, hence its name, contracted kidney. The capsule is thickened and firmly adherent, its removal tearing off portions of the kidney substance. When the capsule has been stripped off the surface, the kidney is seen to be covered with fine granulations. These are of a lighter color at the tips and darker at the bases. Small cysts are visible and characteristic. There is an excess of fat about the organ. On section the kidney substance is found to be tough. All parts of the organ show gray radiating striæ which are found to be new formations of connective tissue. The cortex is thinned and irregularly defined. The Malpighian bodies are many of them obliterated. The medullary rays are obscured.

There is a formation of round cells in the cortical part of the kidney so that a kind of granular tissue is found. From this the new connective tissue is developed and gives a great increase in the interstitial sub-

stance. This change first occurs about the Malpighian bodies. It encroaches on the glomerular walls, these in turn become thickened and encroach on the glomeruli themselves until there is nothing there but a mass of connective tissue. The tubules are also encroached upon and obliterated. There is cloudy swelling of the tubular epithelium followed by waxy or fatty degeneration. The epithelium is shed and forms casts as in the kidney of parenchymatous nephritis.

In the interstitial kidney cysts are formed by the squeezing and crowding of the tufts and tubules by the new tissue, and the consequent retention of the urinary contents in these little sacs. The blood-vessels of this form of kidney are thickened. There is an hypertrophy of the long and circular fibres of the muscular coats. In the glomeruli the blood-vessels may be destroyed by the advancing sclerosis. Thoma has found that the outflow of blood under a given pressure is much lessened in the contracted kidney.

Vascular changes: In chronic Bright's disease of the kidneys changes of the vascular system take place in parts of the body other than the kidneys. Roberts divides the vascular changes into three classes: (1) Simple hypertrophy of the left ventricle without valvular lesion. Bright was the first one to point out this class in his original communication. (2) Valvular defects coexist with Bright's disease. The valvular lesion is usually secondary, although it may exist separately. (3) Chronic nephritis may be secondary to the heart lesion.

There is frequently an hypertrophy of the heart. This is most often found with the contracted kidney. It may accompany parenchymatous nephritis. The general tendency of belief is that the obstruction to the circulation in the kidneys causes an increased pressure in the arteries. The heart and arteries, therefore, have constantly to exert more pressure to force the blood through. This in turn causes hypertrophy of the left ventricle, and a thickening and hypertrophy of the muscular coats of the arteries result.

Dickinson says cardio-vascular changes are constant, especially in the contracted form of kidney. Arterio-capillary fibrosis, or arterio-sclerosis, as it is also called, is a fairly constant accompaniment of chronic interstitial nephritis. When this disease (arterio-sclerosis) was first described by Gull and Sutton, they advanced the proposition that the disease was general, and that the contracted kidney was merely the result of a general process. This idea has not received the unqualified support of other observers. Osler[19] says he believes that arterio-sclerosis precedes the contracted kidney oftener than is generally supposed. He says the disease of the arteries may follow the kidney lesion.

Ocular changes: The only other constant change found in chronic Bright's disease is in the eye. The patient complains of impaired vision. On examination the eyes are found to be affected. There is a haziness of the retina and optic disc. The optic papillæ are swollen and have a clouded and indistinct outline. Extravasations of blood are seen. The veins are tortuous. Numerous white spots are seen, varying in size and scattered about the neighborhood of the optic disc. These are found to be foci of fatty degeneration.

A rarer form of eye trouble is sudden and transient blindness, most often found in the acute nephritis of pregnancy or of scarlet fever. This must be of central origin, as no retinal changes are found.

Exciting causes: Many cases of chronic Bright's disease are of insidious onset and are first discovered by accident. Cases of this nature cannot always be accounted for. Occasionally the acute disease runs into a chronic form.

Diabetes mellitus causes a few cases. Malaria is held by some observers to be an important factor in the production of chronic Bright's disease. Osler says he has never observed such an origin. In the Johns Hopkins[20] Reports for 1895 will be found an analysis of malarial fever as it exists in Baltimore. Of several hundreds of cases the subsequent appearance of acute nephritis is noted three times. Chronic nephritis is not mentioned. Thayer and Hewetson were the authors of that report. Heredity is a predisposing cause. It is common for a number of cases to occur in the same family. Grief and worry undoubtedly cause chronic nephritis in some subjects. Lead is another potent cause of chronic Bright's. Workers in industries in which lead is used are exceedingly liable to develop the contracted form of kidney. In England gout causes many cases. In the United States gout is an unimportant factor. Some cases are due to the irritation of impacted calculi. Others are caused by the upward extension of cystitis or inflammation of other of the urinary organs.

Exposure is probably the most common causative factor.

Chronic Bright's disease is one of temperate climates. The varying changes in temperature are held to account for many cases. Persons who are exposed to sudden changes of temperature in their work are prone to the disease. It is most common in the poorer classes among those who are exposed to hardship and privation. Habitual users of alcoholic liquors are frequent subjects of chronic Bright's disease. Many observers believe that the alcohol itself is responsible. Dickinson, however, considers the subject at length and combats this theory. It is well known that the habitual drinker is less able than others to withstand or resist disease. He is also exceedingly liable to expose himself and thus to produce nephritis. Experimenters have never been able to produce nephritis by the use of alcohol in animals. Tuberculosis causes some cases. Syphilis may produce the disease, especially the contracted kidney.

From one-third to one-half more men than women are affected. Roberts holds that this disproportion is not so great during the child-bearing period, when the sexes are more evenly attacked. He asserts that this is a proof that pregnancy is a real causative factor.

The disease is rare in infancy and in extreme old age. It is most common during late middle life.

Symptoms: Chronic nephritis is an affection that may last from one month to many years. A few patients recover, the majority eventually die. The onset is most often insidious and the disease is usually discovered by accident. Patients really ill of Bright's disease will present themselves with symptoms pointing to the nervous, vascular, or digestive systems so often that it is always wise to resort to a urinary analysis before making a positive diagnosis. It is my rule to examine the urine of all patients in private practice no matter what the ailment.

In chronic nephritis the urine varies in amount from day to day. In the parenchymatous form it is usually diminished in quantity, is dark in color, of slightly increased specific gravity, and contains albumin. It resembles the urine of acute nephritis. In typical cases of the interstitial variety the urine is increased in quantity and is of low specific gravity; this may be as little as 1.010. Albumin may be present only to a slight extent, or it may even be absent for a time. As the disease draws to a close, however, albumin rarely is absent altogether. In all forms of chronic nephritis, toward the end of life, the quantity of urine is diminished. In one case of an acute exacerbation of chronic interstitial nephritis under my care during the summer of 1898, the patient passed an average of less than half an ounce of urine for each

twenty-four hours for three weeks before death. Micturition is more frequent than is normal. The patient, as a rule, is obliged to pass urine during the night. This indeed may be the first symptom for which the patient seeks relief. The urine is very apt to irritate the parts. Besides the appearance of albumin in the urine, as noted above, in all forms of chronic Bright's disease there is diminished execretion of urea and of the mineral salts. This was first noted by Bostock,[21] who made the chemical analyses of the urine in Bright's original cases. Various observers have since that time added to the knowledge extant concerning the chemical constituents of the urine of chronic nephritis. When the urine is scanty and the specific gravity increased we may have a larger percentage of urea in the water, but the total quantity for the twenty-four hours will fall below normal. When the urine is increased in quantity and the specific gravity is low, the percentage of urea is low, but the total amount for the twenty-four hours may not be greatly lessened. Toward the end the excretion of urea is greatly reduced. I have seen it as low as eight grains in the twenty-four hours.

Within the past few years Purdy[22] has called attention to the diminution of the phosphates in chronic Bright's disease, especially in the urine from the contracted kidney. More recently Laidlaw[23] has gone so far as to say "that a deficient excretion of phosphates in the urine is the only constant urinary symptom of chronic nephritis with interstitial changes; it is more constant than albumin, more constant than the low specific gravity or increased quantity of the urine." Laidlaw suggests for this symptom the name of "oligophosphaturia."

In the sediment granular and fatty casts predominate. Epithelium from the bladder and kidneys is found. Blood corpuscles and pus cells are also frequently found. The sediment in chronic interstitial nephritis is less than that in the parenchymatous form.

A good many cases of chronic Bright's disease discover themselves first through a puffiness about the eyes, or through œdema in some other part of the body. Occasionally cases progress to the end without œdema. This does not often happen. As mentioned when discussing the œdema of acute nephritis, œdema will usually be found if carefully searched for. The chronic parenchymatous kidney is the one that produces dropsy to the greatest extent. It develops slowly and constantly increases, until toward the end of life it may cause dyspnœa by œdema of the lungs, or by pressure in the pleural or abdominal cavities. Ascites sometimes develops to an astonishing extent. I have several times removed fifty and sixty ounces of fluid from the abdomen.

The dropsical fluid accumulates not only in the cavity of the abdomen, but there may also be an effusion into the walls of the intestinal tract and a consequent diarrhœa. The dropsy may become very great, and yet, under appropriate treatment, almost entirely disappear. If the case happens to be one of the rare ones that end in recovery, the œdema may cause no further trouble. As a rule, however, the dropsy recurs again and again until the point is reached where medicinal treatment has no further effect. Then the only resort is to palliative measures until death closes the scene. The favorite places for the appearance of œdema have been indicated under the symptomatology of the acute form of the disease. It begins in the loose areolar tissue about the orbits and genitals. Flint says a good place to detect slight œdema is over the sternum. When the heart's action fails, the dropsy appears in dependent portions of the body. The labia and scrotum may become swollen to the size of a man's head. The face may lose all semblance of a natural appearance and look more like a balloon than anything else.

The third of the great trio of Brightic symptoms is uræmia. This may manifest itself as a dull throbbing headache—a very frequent symptom in chronic interstitial nephritis. In my experience the common form of headache is occipital. Other observers have noted it more frequently in the frontal region. We may get cerebral nausea and vomiting as a result of the uræmic poisoning. Uræmic vomiting is said to have an ammoniacal odor. If the vomited matter is acid it is said to evolve ammonia on the addition of caustic potash. The patient may be drowsy or stupid, or he may be talkative and start and twitch. Uræmic coma and convulsions are comparatively frequent. Either condition may be the first to call attention to the disease. Delirium is rare. I have seen one case of it. It appeared suddenly and would disappear after a quiet sleep induced by hyoscyamus. This occurred a number of times during the last few weeks of life.

If the brain symptoms are slight, there may be blurred vision, light flashes, and other disturbances of the sense of sight. Cases have been reported of toxic dyspnœa due to uræmia. My own experience has been that dyspnœa is always associated either with œdema of the lungs or with pressure from hydrothorax or ascites.

Vascular changes are marked in chronic nephritis. Hypertrophy of the heart or valvular lesion is associated with nearly all cases. The pulse is characteristic of the vascular condition it is associated with. In parenchymatous nephritis there is apt to be a weakened pulse with increased rate. Valvular lesions are often found with this form of kidney. In the interstitial form of the disease the pulse is full and strong. Owing to the sclerotic changes that take place in the walls of the arteries the pulse continues to feel hard to the end. The heart sounds are strong. The second sound is accentuated. The apex is low and to the left. Palpitation is common.

Anæmia accompanies chronic Bright's disease. During transient disturbances of the circulatory system cyanosis may develop. In far advanced cases, when the heart is unequal to the continued strain, cyanosis of the dependent parts of the body is common. I have seen but one case in which the cyanosis was general for any length of time. The patient was waterlogged and cyanosed when brought to the hospital. He lived about a week in that condition. Cyanosis and anasarca were more marked than in any other case that has passed under my observation. Angina pectoris is occasionally present as a symptom. I have had one such case. Purpura may also occur. Cerebral hemorrhage is quite a common symptom, especially in chronic interstitial nephritis.

In the lungs bronchitis is commonly associated with the chronic as well as with the acute Bright's disease. There may also be cough and dyspnœa. The dyspnœa may be due to uræmic poisoning or to pressure of the dropsical fluid. Pleurisy is often found with chronic Bright's disease. It occurs most often in connection with a heart lesion. The symptoms found in the gastro-intestinal canal are numerous. They often cause a mistake in diagnosis. I have seen nausea and vomiting occur often in chronic Bright's disease. They may be due to uræmia, or they may be due to actual gastric disease. Burning pains in the stomach are sometimes complained of. One patient of mine complained of soreness across the abdomen. Diarrhœa often occurs, especially in dropsical subjects. This is sometimes due to the swollen condition of the intestines which causes them to act abnormally. It may be accompanied by cramps. There may be a great deal of flatulence.

The symptoms found in the nervous system are numerous and varied. Some are due to the deteriorated blood, others are due to uræmic poisoning. Headache

frequently occurs. Sleeplessness is another distressing symptom, especially toward the end, when it is apt to be aggravated by dyspnœa. The patient may be drowsy, dull, or in a profound stupor. This latter is due to uræmia. Uræmic convulsions are similar in their manifestations to epilepsy and are quite common. Coma also is quite common. These two symptoms, convulsions and coma, are often preceded by amaurosis. They may be preceded by vertigo, numbness of the hands and feet, cramps in the muscles. This last group may for a long time be the only manifestation of uræmia.

One patient of mine first consulted me because of this peculiar numbness. Later she complained of "sinking spells," which she brooded over. Then she got the notion that her family was neglecting her. Noises annoyed her. Music, which she had formerly been very fond of, caused her to weep. In a word, the condition simulated one of melancholia. Another patient, already referred to, developed violent delirium. He believed a conspiracy had been formed by his wife and physician to kill him and to get his property away from him. It required considerable diplomacy to manage him. I hope never to see another case like it.

One of the diagnositic signs of chronic nephritis is albuminuric retinitis. A patient will complain of blurred vision. An ophthalmoscopic examination will show the characteristic changes. This consists in the appearance of an indefiniteness in the outlines of the optic papillæ. The retina is puffy-looking. The veins are engorged and tortuous. Little white spots of different size are scattered about the optic disc.

Another eye symptom that has been mentioned several times is sudden blindness. This augurs ill. It sometimes precedes the onset of acute uræmia. The blindness is only temporary in any case. No anatomical changes have been discovered in association with it.

The temperature of chronic Bright's disease is most frequently below normal a very little. During the final weeks it may vary from 99° to 100° F. The appetite is lost. The skin is dry and pale. There may be intense itching, accompanied or not by a deposition of urea on the surface of the body. As life draws to a close the patient exhibits all the signs of profound disorganization. There are twitching and picking at the bed-clothes. The patient slides to the foot of the bed. Urine and fæces are passed involuntarily. The patient is unconscious.

Complications: An acute nephritis may develop in the course of a chronic condition. This may present such a classic picture of the acute disease that the chronic condition remains undiscovered until the necropsy. Chronic nephritis is subject to all the complications of the acute disease. Hemorrhages from the mucous membranes may occur, as epistaxis and hæmoptysis. Alternate constipation and diarrhœa is more or less common; this may be due to catarrhal conditions, to uræmia, or to œdema. Secondary inflammations of the pleura, lungs, pericardium, peritoneum, and even of the integument may complicate the chronic nephritis. Numerous nervous, digestive, and vascular changes are associated with it; most of them have been noted in the symptomatology. Chronic Bright's disease and pulmonary phthisis are often found associated.

Diagnosis: The diagnosis of chronic Bright's disease, early in its history, is frequently overlooked. The onset is insidious, and the disease may progress for months and years before it is even suspected. In the majority of cases the discovery of the existence of chronic nephritis is made by accident, many such being found on examining candidates for life insurance. It is quite a common affection in this country. It is important that chronic Bright's disease be discovered early, for if promptly and properly treated much can be done to prolong life. It is wise, therefore, to make analysis of the urine a routine measure in all cases, whether nephritis is or is not suspected. For several years I have made it my rule to examine the urine of every new patient and to keep a record of the result on file for future reference. A number of times I have in this way discovered that a patient was suffering from chronic Bright's disease, and in each instance I believe the patient has been the gainer.

Typical cases of chronic parenchymatous nephritis, in which the urine is scanty and contains albumin, and there is œdema, are not difficult to diagnose. Nor are cases with a history of profuse urine of low specific gravity, slight œdema, accentuated second sound of the heart, indicating the contracted kidney, at all confusing.

Acute exacerbations of a chronic nephritis can be mistaken only for the acute disease. Without a history these cases cannot be differentiated. This makes no difference in the treatment, as both groups of cases require the same. It does make a difference in the prognosis, because the rule is for the acute case to result in recovery and for the chronic case to be fatal.

The varying symptoms of chronic nephritis may simulate those of any of the conditions already noted in discussing the diagnosis of acute nephritis. That section must be read before going on to the consideration of the other disease that may be mistaken for chronic Bright's. The urine must be carefully studied in all doubtful cases, not once, but many times. Even then a positive diagnosis can be made only by carefully weighing all the evidence.

Chronic indigestion is often treated without the fact being detected that it is caused by Bright's disease. Patients with gastro-intestinal troubles should always be carefully examined for further evidences of nephritis, as this is one of the characteristic methods of its development.

Other patients will exhibit symptoms of neurasthenia, of melancholia, of neuralgia, of rheumatism. All such patients must be watched for the development of Brightic symptoms.

Anæmia is one of the most prominent symptoms of nephritis. Any case presenting anæmia as a symptom needs to be watched.

It is unnecessary, perhaps, to particularize further. A patient presenting with constant disturbance of the digestive system, of the nervous system, of the vascular system, or of the respiratory system, should put the physician on his guard. Groups of symptoms of any of these parts, especially if of obscure origin, should arouse the suspicions of the medical adviser. Even if changes cannot at first be found in the urine, that does not imply that they may not later develop. If this fact is always borne in mind and acted on, mistakes will not be so apt to occur. Finally, some cases will escape the most careful diagnostician until help is impossible.

Prognosis: The prognosis of chronic Bright's disease is bad. Nearly all patients die of it. The disease may last from several months to ten years or more. A few observers have reported cases of cure. I have never seen or personally known of an actual cure. I have seen many patients much benefited by treatment and kept alive for varying lengths of time. Acute exacerbations may be met and subdued with appropriate treatment. But a time will come in nearly every case when that becomes no longer possible.

Death may occur from any of the causes that effect a fatal termination in acute Bright's disease. Cerebral apoplexy is the cause of death in quite a percentage of cases.

Treatment: When acute symptoms develop during

chronic Bright's disease, the patient has to be treated in all respects as if it were an acute case.

If the patient is found to be suffering from chronic Bright's disease in a quiescent state—that is, if he is in fair general health—he must be cautioned against catching cold. It would be preferable to have him removed to a warm climate. Wherever he lives he ought at all times to wear wool next the skin—woollen underwear by day, woollen pajamas by night. Great care must be used to keep the skin functionating. For this purpose there is nothing so good as a sponge bath, followed by a good rub-down. This kind of bath is best taken with moderately cool water on rising in the morning. Every other day is often enough. One or two hot baths—tub baths—should be taken through the week, preferably at night just before retiring.

The diet of the chronic Brightic in apparent fair health is a mooted question. My opinion is in favor of a liberal diet. Red meat is permissible once a day. Chicken, eggs, most kinds of fish, vegetables, fruit, milk, all may be used. Fat, greasy foods, and rich, heavy pastries must be avoided. Tea and coffee may be used if desired. In the way of alcoholic liquors, I like my patients to stop their use altogether. If something of the sort must be used, claret and diluted whiskey—at the strongest one part whiskey to four of water—are the least harmful. I prohibit all malt liquors.

If there is a history of syphilis, iodide of potassium will almost invariably benefit the patient.

Besides the remedies mentioned under the treatment of acute Bright's disease, there are one or two that need special notice here. Bichloride of mercury was mentioned before. It is one of the best of remedies in chronic nephritis. It will diminish the amount of albumin and may cure the patient. I have also found lead to be a good remedy, especially in the contracted kidney. Millard mentions its use.

Toward the end of life, when the heart begins to fail, there are a number of remedies that may be of service. Infusion of digitalis is one of the most frequently used. It ranks high as a diuretic and as a heart stimulant. My own experience with it, however, I must confess to have been disappointing. I like caffeine better and have seen it do good work. The heart's action becomes stronger, the urine increases in quantity, and the patient is less nervous. Strychnine is a good heart stimulant, but its use must not be continued for too long a time. If it is, the patient gets into a neurasthenic condition that is distressing. The bowel becomes paralyzed. It is a dangerous remedy to give for continued periods. It will make the patient worse if care is not used.

For emergency use in threatened heart failure, camphor in drop doses, repeated every five minutes if necessary, is my first choice. It is one of the most prompt and diffusible of heart stimulants. For hypodermatic use at such times brandy or ether may be used.

One of the most distressing symptoms in advanced cases of Bright's disease is sleeplessness. Morphine is usually recommended. I have so often seen it excite instead of soothe the patient that I do not use it any more. If I use opium at all I prefer codeine. I give it in one-eighth of a grain doses. It is safer and does the work more effectively for me. The bromides and chloral I object to on general principles. If the sleeplessness is not caused by actual physical pain, but is more of a nervous phenomenon, I sometimes use trional. I give it in the usual fifteen-grain dose. In such cases it has proven itself very satisfactory.

## MUCOCELE OF THE MAXILLARY SINUS.*

BY W. SCHEPPEGRELL, A.M., M.D.,
NEW ORLEANS, LA.,
PRESIDENT WESTERN OPHTHALMOLOGICAL AND OTOLARYNGOLOGICAL ASSOCIATION.

IN reviewing the older literature on the subject of diseases of the maxillary sinus, the term "hydrops antri" is repeatedly met with, especially in works on general surgery. The title is now rarely seen, and it is generally admitted that a hydrops cannot form in the maxillary sinus on account of the character of the mucous membrane lining this cavity. The cases referred to in the former literature of this subject were probably due to other conditions, the word "hydrops" indicating an error in the diagnosis.

While the term "hydrops antri" has been abandoned, that of "mucocele" of the antrum of Highmore is occasionally met with. In Charles Burnett's "System of Diseases of the Ear, Nose, and Throat," Joseph H. Bryan,[1] while admitting that hydrops in its true sense—that is, an inflammation characterized by a serous secretion—cannot develop in the maxillary sinus, believes that mucocele, indicating an accumulation of mucus, the result of a catarrhal inflammation of the mucous membrane due to extension from the nose, may still exist in cases in which the ostium maxillare becomes closed so that the accumulated mucus cannot escape. The anatomy of the mucous membrane of this cavity, however, indicates that the term "mucocele," especially presenting the violent symptoms that are usually ascribed to this condition, cannot be considered as a pathological entity, this being also the opinion of Zuckerkandl[2] and the majority of investigators who have given attention to this subject.

The lining membrane of the maxillary antrum consists of two layers, the one forming the periosteum of the bony wall and closely adjusted to all its anfractu-

* Read before the annual meeting of the American Laryngological, Rhinological, and Otological Society, Cincinnati, June 2 and 3, 1899.

osities, and the other the mucous membrane proper. In the latter are found glands of the muciparous order, some being of acinous and others of tubular formation. These glands are very much scattered except in the upper part of the cavity, where they are found in a somewhat larger number. On account of the paucity of these glands, the maxillary sinus secretes only sufficient to moisten the surface of the cavity, this fact having already been pointed out by Burns[3] in 1821. There is a close adjustment between these secreting glands and the absorption by the lymphatics of this cavity, so that without the loss by evaporation from the inspired air, as in the nasal cavities, there is no excess of moisture.

A careful investigation of the cases which have been published under the title of "hydrops" and "mucocele" indicates that by far the majority of these cases were due to cysts, and even some of the cases of empyema were probably also of cystic formation. These cysts, which may be single or multiple, may be caused by dilatation of a follicle in the mucous lining of the antrum, to cystic degeneration of a polypus, or to dentigerous cysts, either internal or external, which may reach the maxillary sinus by erosion and present all the characteristics of an antral cyst.

While empyema of the antrum is not of infrequent occurrence, cases exhibiting the symptoms of retention, dilatation, and deformity, whether published under the term hydrops, mucocele, or cysts, are of comparatively rare occurrence. That a cyst which is ruptured into the nasal cavity may be mistaken for empyema is easy to understand, and a differential diagnosis presents so much difficulty in some cases that a mistake can easily occur. If a cyst completely fills the maxillary sinus, and spontaneous rupture takes place into the nasal cavity and pathogenic micro-organisms invade its contents, we will have all the evidences of an empyema, and a correct diagnosis can be arrived at only by the most careful investigation. If the walls of the cyst are closely adherent to the sides of the antrum, and an artificial opening is made through the alveolar process, the probability of correcting the error becomes greatly diminished, and no doubt some of the cases of rapid cure of a supposed empyema of long standing are due to this cause. Cysts may be present in the antrum for an indefinite time, as they usually give rise to no marked symptoms until the distended walls begin to encroach upon the normal limits of the sinus. As already stated, the diagnosis is not always a simple matter. Transillumination, which is an important measure in empyema, is here negative as compared to the normal cavity, and the same may be said of the Roentgen rays. The thin wall of the cyst and its translucent and frequently transparent contents offer little obstruction to the luminiferous rays, so that the difference from the normal cavity is practically *nil*. In fact, it is not impossible that the contents of the cyst may have some converging effect on the light, so that the transillumination is actually increased. Nor would the *x*-rays offer more satisfactory results in such cases. When the cyst formation has developed to such a point that the symptoms of distention are present, the diagnosis is greatly facilitated. Ectasis may be due either to a cyst or a solid tumor, and transillumination and the *x*-rays easily enable us to differentiate between the two.

Cysts of the antrum have sometimes been mistaken for more serious conditions, and several cases are on record in which preparations were made for the surgical removal of the whole superior maxilla under the impression that the symptoms were due to a malignant neoplasm, when the conditions presenting themselves were feund to be caused by a dilated cyst.

The prognosis of cyst of the maxillary sinus is better than in cases of empyema of long standing. We are all familiar with the obstinate character of many cases of empyema when the pathological condition has existed for a considerable time. Cysts, on the other hand, frequently yield promptly to treatment, and, even in cases in which a spontaneous rupture has taken place and the secretion is infected with pathogenic micro-organisms, the prognosis is much more favorable than in cases of chronic empyema of the maxillary sinus. In some of the published cases of rapid cures of long-standing empyema of this cavity the disease was probably cystic.

Several cases of cyst of the maxillary sinus are reported by Kunert,[4] in which the symptoms strongly suggested empyema, but in which the real cause was a cyst of the maxillary sinus. Lesniowski[5] reports a case of a patient who had suffered for a year and a half from pain and swelling similar to that found in the cases formerly reported under the title of "hydrops" of the maxillary sinus. In this case also the cause was found to be a cyst of the maxillary sinus, complete relief following its extirpation. A case under the title of "mucocele" is reported by Baumgarten,[6] the patient being a boy, aged thirteen years, in whom a spherical swelling the size of an apple appeared under the left zygomatic process. The skin was normal, but weak fluctuations could be detected at the canine fossa. The hard palate was depressed on the left and fluctuations could also be felt there. The nasal cavities were normal. Puncture through the canine fossa was followed by the discharge of serous matter. The treatment was afterward continued by irrigation, and the patient made a complete recovery. The author believed this to be a case of mucocele due to obliteration of the ostium maxillare, but the symptoms and history leave no doubt that it was a cyst of the maxillary sinus.

A case of "hydrops" of the maxillary sinus in a girl aged thirteen years is reported by Cassalette.[7] The reading of this case leaves little doubt that the symptoms were due to a cyst of the maxillary sinus. Charles H. Knight[8] reports a case of cyst of the maxillary sinus, this being of interest as it also presents the majority of the symptoms ascribed to "hydrops antri" or "mucocele." The patient, a man aged twenty-nine years, complained of no pain, the only symptom being an obvious deformity in the left malar region, the mass pushing the upper lip forward and the dilatation extending as far as the lower margin of the orbit. There was no malformation of the roof of the mouth, and the nasal fossa on the affected side was quite normal. On incision, it was found that the wall of the cyst was so firmly adherent to the bone that the lining membrane of the antrum seemed to constitute the cyst wall. About two ounces of thin, slightly turbid fluid were evacuated. A director was passed with some difficulty from the antral cavity into the nasal fossa through the ostium. No suppuration developed, and four months after the operation there had been no recurrence.

In concluding this article I will give the clinical history of a case which recently presented itself in my practice, of a cyst of the maxillary sinus, in which all the characteristic features ascribed to the old cases of "mucocele" of the maxillary sinus were found. The patient, a man aged forty-two years, applied in February, 1899. He complained of severe pain in the region of the left cheek and pressure on the eyeball. The pain had existed for several days, but for the past twenty-four hours had been so severe that the patient was entirely unable to sleep or lie down. The fulness of the left side of the face and throbbing were still violent when the patient was examined, although some relief could be obtained by holding the parts with his hand. Pain on pressure was very severe and

radiated over the whole area of the superior maxilla. The pain was especially localized in the region of the second bicuspid on the left upper side, the tooth having been extracted fifteen months before. When removed, this tooth was found to be diseased. Since then there had been occasional pain on the left side of the face, but not of a grave character, and there had been no swelling at any time. The symptoms indicated pressure from the left antrum of Highmore. The transillumination test exhibited no difference in the amount of light transmitted on either side, showing that the pressure was not due to a solid tumor. Had the cavity been filled with purulent matter, as in empyema, there would probably also have been a noticeable decrease in the light on this side, although, as we know, transillumination is not always a reliable test. The case thus presented all the symptoms of the older cases of "hydrops" or "mucocele." As a result of examination, a diagnosis of cyst of the antrum was made. The symptoms being very severe and the patient declaring emphatically that he would be unable to stand the suffering another night, it was decided to make an exploratory puncture in the cavity without further delay. The tissues in the site of the extracted tooth having been cocainized, a small trephine was passed through the alveolar process into the cavity. This was followed by a negative result. A probe, however, on being passed through the opening met with a resisting membrane. When this was punctured a viscous, non-fetid secretion was evacuated, the patient immediately expressing a sense of relief. A small cannula was then passed into the cavity, but all efforts to force a solution through the ostium maxillare were unavailing. A light packing was placed in the opening in the alveolar process, and an appointment was made for the following morning for a more radical operation. The next day the patient was anæsthetized and a large opening made in the canine fossa. The cyst membrane was then removed with a curette, but with considerable difficulty, as it was adherent in many places. After the cavity had been thoroughly curetted, the solution was again passed through the antrum, this time finding its way through the ostium maxillare into the nasal passage. The cavity was carefully packed with five-per-cent. iodoform gauze, which was removed twenty-four hours later, when it was irrigated with a mild boracic-acid solution and again packed. After this treatment was continued for three days, the irrigation only was practised, and a week later the patient was sent home with instruction to syringe the cavity with warm boracic-acid solution twice daily. A month later the patient was again seen and appeared practically well. The fistula had almost entirely closed. At no time had there been any marked fetor. Occasionally, when the cotton which closed the fistula to prevent the entrance of foreign matter was left in position too long, a slight odor developed, but disappeared with the next washing.

The case illustrates the difficulty of making a diagnosis between cyst of the antrum and the so-called "mucocele." Had the walls of the cyst been adherent at the point at which the antrum was first punctured, or had the trephine passed through the wall into the cyst cavity, the illusion that it was a mucocele with obliteration or obstruction of the ostium maxillare would have been very strong. Had a spontaneous opening taken place into the nasal cavity and the retained secretion infected with pathogenic micro-organisms, the differentiation between cyst and empyema would have presented the greatest difficulty.

## THE EVILS OF THE RITUAL PRACTICE OF CIRCUMCISION.

BY ALBERT MILLER, M.D.,
NEW YORK,
ATTENDING PHYSICIAN TO THE EAST SIDE DISPENSARY.

ALTHOUGH a great deal has already been written concerning circumcision, yet nothing has been done to eradicate the evils of its practice on Hebrew children. I do not intend in this article to attack circumcision as a religious rite, but simply to draw the attention of the profession to the evils existing in its performance. I am surprised that so little has been written concerning this important subject thus far. From time immemorial, it has been practised by almost the entire Semitic race, and especially by the Hebrews since the time of Abraham.

It is perhaps unnecessary for me to point out its advantages, for they are too well-known even to the laity; very frequently even the uncircumcised adult is forced to resort to it in order to prevent the development of inflammatory conditions in the redundant foreskin. And to-day we have many advocates of universal circumcision, on the ground that prevention of disease is easier than its cure.

History records that the Hebrews escaped great epidemics more readily than the other races with whom they lived. "Different causes have been assigned for this higher vitality of the Jewish race, and it were wise to seek for these causes, since that race which presents the strongest vitality, the greatest increase of life, and the longest resistance to death must in course of time become, under the influence of civilization, dominant. We see this truth indeed actually exemplified in the Jews; for no other race has ever endured so much or resisted so much. Persecuted, oppressed by every imaginable form of tyranny, they have held together and lived, carrying on intact their customs, their belief, their faith for centuries, until, set free at last, they flourish as if endowed with new force. They rule more potently than when Solomon in all his glory reigned in Jerusalem. They rule, and neither fight nor waste."[1] It is claimed by some historians that circumcision is a great factor in causing the differences that exist between the Jewish race and other races. The Scriptural law reads as follows: "This is my covenant, which ye shall keep, between me and you and thy seed after thee: every man child among you shall be circumcised. And ye shall circumcise the flesh of your foreskin, and it shall be a token of the covenant betwixt me and you."

In Turkey, the uncircumcised is regarded as impure and the Arabs practised circumcision long before the days of Mohammed. Many savage tribes also practised circumcision as a religious ceremony.

To-day, many Hebrews look upon this law simply as hygienic and discard any religious significance, and of course this is the view held by the medical profession.

Every one will admit that the operation requires a certain amount of surgical skill, and it is not so simple as to warrant its performance by a layman; yet ritual circumcision is always performed by a layman. There is a class of men living among the Jews who are

[1] Richardson: "Diseases of Modern Life."

termed "mohelim," whose function it is to perform this operation. These men possess neither medical knowledge nor surgical skill; they have no idea of the existence of germs, understand nothing about the theory of sepsis and antisepsis, and in a great many cases are even void of personal cleanliness.

Any layman with the slightest pretension to piety may become a "mohel"; and he usually gets a fee which many a young surgeon would only be too much pleased with. I am not surprised that the Jewish community, like any other community, can be imposed upon; but that the medical profession should tolerate men who practise without a license and who are a danger to the community, I cannot understand. Many of the medical practices of midwives, barbers, faith curists, Christian Science healers, and the like have been brought to the attention of the public of late, but not a voice has thus far been raised against these "mohelim." The public scarcely realize the dangers of such an apparently simple operation. They do not know that the child is very apt to become infected with disease and perhaps die from hemorrhage. As a means to stop hemorrhage from the penis, the "mohel" takes it in his mouth and sucks the first blood off directly after the circumcision. The child is thereby exposed to the danger of inoculation with various diseases, among which syphilis and tuberculosis are the most prominent.

Vaccination is by far a simpler operation than circumcision, but if any layman should attempt to vaccinate he would be promptly arrested for illegal practice and fined. Why, I repeat, should this not be the case with the "mohelim"? Circumcision as performed by them is an evil which should be done away with, and doubtless means can be discovered to suppress the abuse without offending religious prejudice.

109 Henry Street.

## HERNIA OF THE VERMIFORM APPENDIX.

By L. L. HILL, M.D.,

MONTGOMERY, ALA.

As surgeons have been prodigal in the donation of their time to the study of inflammatory conditions of the vermiform appendix, it may not be amiss to consider this important part of the economy as it figures in another rôle—the appendix in a hernia. Recently two cases have come under my observation, which I will report:

Case I.—Henry M——, negro laborer, sixty years of age, had for twenty-five years a partly reducible scrotal hernia on the right side. He was seized after a violent coughing spell with severe pain, and noticed that the size of the hernia had perceptibly increased. He continued to suffer for eight hours, when I was called, March 12, 1899, and found him with an anxious expression of countenance, restlessness, and almost continuous retching and vomiting, which, however, was not feculent. The bowels had not acted and the abdomen was somewhat distended. After a brief trial of taxis, under an anæsthetic, without result, I proceeded to perform herniotomy. Opening the sac I found the cæcum and vermiform appendix. The latter was eight or ten inches in length and was firmly adherent to the sac, which accounted for the irreducibility, and the constant stretching was the cause of the unusual lengthening of the viscus. The appendix is usually adherent, as is shown by the valuable statistics of Dr. Coley, in which he reports adherence to the sac in eight out of nine cases. This is easily accounted for when we consider the tendency of the appendix to inflammatory action. The operation was completed after the method of Bassini, and the patient made a good recovery.

Case II.—Mrs. M——, forty-eight years of age, stated that for three years at times she had observed an enlargement under Poupart's ligament which upon manipulation would disappear. On April 5th she noticed a tumor about the size of a hen's egg, which was tender to the touch and became more and more sensitive until the 8th, when Dr. R. S. Hill was summoned and advised that I be called and that an operation be performed at once. I found the patient's pulse 100 and temperature 100° F. She complained of considerable pain and was vomiting occasionally. The bowels had moved freely as the result of two drachms of Epsom salts, administered before either of us saw her. Making an incision upon the tumor, I encountered about two ounces of fluid, and found a strangulated vermiform appendix at the crural ring. The constriction was so great and the adhesions were so extensive that it was necessary to incise Gimbernat's ligament before freeing the appendix. Drawing the healthy portion of the viscus into the wound I ligatured it about a quarter of an inch from the blind gut and removed the diseased part; after cauterizing with carbolic acid, I pushed the stump into the abdominal cavity and closed the wound. The patient made an uninterrupted recovery.

It is interesting to study the methods by which the vermiform appendix finds its way into a hernial sac. According to Mr. W. McAdam Eccles, of London, the appendix may be abnormally lengthened, either congenitally or as the sequel of attachment. Or, the mesocæcum being unusually long, the viscus is permitted to reach the hernial ring. It could easily enter a congenital right inguinal hernia, but it is more difficult to explain its forming its own sac. I believe with Mr. Eccles that it is possible that "the appendix itself may be the producer and the entire contents of a right inguinal or a right femoral sac, and in a few very rare cases of a left inguinal one," but that it is much more probable that the appendix has an accompaniment which causes the hernia; and the former with its inflammatory tendency becomes adherent and irreducible, whereas the latter returning to the peritoneal cavity allows the sac to contract to the size of the contained viscus. Specimen 2,635 in the museum of the Royal College of Surgeons of London shows the cæcum occupying the upper part of the sac of a right inguinal hernia, which would have been reducible but for the attachment of the appendix at the bottom. Mr. Eccles published in 1896, in St. Bartholomew's Hospital Reports, twenty-nine cases of hernia of the vermiform appendix—sixteen inguinal and thirteen femoral. They were all on the right side excepting one, which was a left inguinal. In two of the cases the appendix was accompanied by other viscera. In one of the May numbers of *The Lancet* Mr. Edmund Owen reports a case of strangulation of the vermiform appendix in the sac of a right femoral hernia at St. Mary's Hospital, London, and Mr. Battle a case of irreducible femoral hernia containing the vermiform appendix at St. Thomas' Hospital. Mr. Chavasse, of Birmingham, England, reports a very similar case in one of the June numbers of the same journal. Dr. Catellani, of Padua, Italy, the home of Bassini, reports a case in the *Annals of Surgery*, December, 1898, of a left femoral hernia containing the cæcum and appendix. Dr. Baiardi records ninety-eight cases of hernia of the appendix, and in only two cases was it on the left side. Dr. Briancon published in 1897 in Paris fourteen cases, all on the right side. At the clinic of Professor Colzi, of Florence, out of fifteen hundred and eighty-six herniotomies the vermiform appendix was found in twenty-seven cases. At Professor Tricomi's clinic in Padua the appendix was found four times in four hundred and twenty herniotomies. Dr. Coley says of four hundred cases of children operated

on at the Hospital for Ruptured and Crippled in New York City, the appendix was found in nine cases.

From the above statistics we should be justified in concluding that the vermiform appendix is found in about one and a half per cent. of hernias, and that in not quite three per cent. of these cases the appendix is found upon the left side. The appendix more frequently forms a hernia in children, being found in a little more than two per cent. of hernias. I have been unable to find the report of a case in which the appendix was the sole occupant of a left femoral sac or an umbilical or ventral hernia.

## Progress of Medical Science.

**The Treatment of Astasia-Abasia.**—The author, Rudolph Funke (*Zeitschrift fur diätetische und physikalische Therapie*, vol. ii., 1899), describes in detail a systematic course of treatment which he has employed with success in a large number of cases of this symptom complex. Holding that the affection is both hysterical and neurasthenic in etiology, he concludes that a logical treatment must embrace both gymnastic exercises and psychotherapy. In the latter regard it is of especial importance that the entire course be conducted by the same physician, and that the patient's confidence be obtained from the start and he be convinced that his disease is readily curable. The patient is put to bed and kept there continuously, and while in the horizontal position is started on systematic movements of the limbs and trunk, which are first done by the attendant, and at the word of command repeated by the patient. Care must be taken that the patient does not with his eyes follow the movements of his limbs, by having him concentrate his gaze on some fixed spot. Then follow passive motions carried out with the patient still in the recumbent posture. After a sufficient lapse of time the patient is allowed to sit up and the same procedures are repeated. The change to the erect position is accomplished by the use of crutches, and as the patient gains confidence these are placed in a more and more slanting position so as to diminish the support they give, and finally dispensed with altogether, the physician supporting the patient by his hands in the axillæ. At this point the act of arising from a sitting posture must be practised, the physician acting in unison with the patient and gradually diminishing the assistance given. The various exercises must be regularly practised until they are promptly and accurately performed. In a similar way the abasia is gradually overcome, and after progression in a forward direction has become possible the more difficult exercises of walking backward, climbing stairs, and prompt starting, stopping, and turning at command are drilled in. At this epoch, and not before, the patient is allowed to leave his bed at times other than his hours of exercise. For perfecting the performance of the more finely co-ordinated movements, some form of apparatus, like the dynamostat, which permits of gradual increase in the resistance, is found very useful. In cases of astasia-abasia of the choreiform or saltatory character the treatment is slightly different. The problem here is a double one, viz., to check the disturbing involuntary twitchings and restore the lost power of voluntary motion. The author describes how this was accomplished in one case by having the patient simultaneously with the motion of his legs perform some other act, such as deep breathing, opening and closing the mouth or eyes, moving the arm, etc. Although this at first was very difficult, the result was most brilliant, and a cure was effected in four weeks. Electricity, medication, and massage are all to be employed as adjuncts to the gymnastic treatment.

**A Case of Multiple Sclerosis with One-Sided Tremor.**—P. Remlinger (*Rev. de Médecine*, vol. 19, 1899) reports a case which showed the following cardinal symptoms: There was an intention tremor of the upper and lower extremities, limited to the right side; exaggeration of the tendon reflexes, more marked on the right side; gait markedly spastic; tremor of the lower lip: diminution in sight due to beginning optic-nerve atrophy; slow speech with monotonous and scanning cadence. These symptoms had been developing for the past six years, during which time the limitation of the tremor to the right side was remarkable, being so constant.

**The Eye in Melancholia.**—Dr. A. Athanassio (*Archives de Neurologie*, May, 1899) speaks of a sign in the eye of melancholics which has not been noted to any great extent. He finds that whereas the light reflex is present, the reflex to accommodation is lost—thus the reverse of the Argyll-Robertson pupil. He explains this by assuming in melancholia a state of aboulia in which the patient will not really make the effort to fix the eye on a definite point.

**A Case of Congenital Impotence.**—Belkowsky (*Allgem. Zeitschr. f. Psychiatrie*, Bd. 55, Heft 5) describes the case of a man who, although married for four years, had never been able to perform the sexual act. In spite of the fact that his genitals were normal in development and his general bodily condition was excellent, he was totally devoid of sexual sensations, had never in his life had erections, and only quite lately had he had some nocturnal emissions, accompanied, however, by only imperfect erections. He was totally indifferent to the female sex, but no trace of sexual perversion could be observed.

**Leprosy of the Lung.**—Babes and Moschuna (*Arch. de Méd. expérimentale et d'Anat. pathologique*, vol. 11, 1899) show that in leprosy the lungs may be affected in a manner similar to that found in tuberculosis. In many cases the lungs may be sound and no tubercle bacilli be found; in others there may be a true pneumonic process with the presence of tubercle bacilli, and again in others there may be no tubercle organisms, but they have found the lepra bacillus. They report two cases of leprous pneumonia with peribronchitic nodes. They also report cases of leprous phthisis.

**The Organotherapy of Diabetes by Means of Liver Extract.**—In the treatment of diabetes up to the present time better results have been attained by the use of liver extract than by means of pancreas extract. Gilbert and Carnot (*Lyon Médicale*, February) report on a series of cases in which they were able to produce a decided reduction in the amount of sugar excretion. Linnosier discusses two cases of diabetes in which the liver extract was administered but without appreciable amelioration of the symptoms. Both of these were, however, aggravated forms of the disease.

**Wounds of the Pericardium and of the Heart, and their Treatment.**—As the result of an elaborate study, based upon an analysis of fifty-four cases collected from the literature, Loison (*Revue de Chirurgie*, January–July, 1899) concludes that the symptomatology of wounds of the heart and of the pericardium do not seem more indefinite than those of wounds of the peritoneum or of some of the abdominal viscera. The diagnosis is as difficult and as delicate in the one group of cases as it is in the other, and it demands all the acumen of the surgeon. The prognosis is not always fatal, as the statistics show. Treatment is not entirely hopeless, as the results of surgical intervention at the hands of numerous operators in a number of cases demonstrate.

# MEDICAL RECORD:

New York, August 26, 1899.

## LABORI'S WOUND AND THE QUESTION OF BULLET EXTRACTION.

THE discussion bearing upon the probable outcome of Labori's wound with the bullet remaining embedded in the muscular tissues of the spine has revived the old question of active surgical interference in such cases. While it must be admitted that there are many controlling circumstances which must determine the particular treatment in individual instances, there are also general principles of management which are quite well established and which necessarily determine the course to be pursued in the large majority of such injuries.

The widely accepted surgical view, that it is always safer and better to remove such missiles when such a course is possible, does not admit of adverse argument. A bullet is thus considered always out of its place when lodged in the human body. The fact that it may in a very small proportion of cases become encysted and give no immediate trouble does not in any sense militate against this general proposition. It should never be a question of taking chances in the latter direction when the ball can be safely reached. With the radiograph to determine the exact position of the foreign body, there is no longer any excuse for aimless incisions or dangerously septic probing.

The main risks which have existed in former operations for extraction are thus eliminated with a corresponding guarantee of sure and speedy healing of the resulting wound. In view of these facts the surgeon who is content to take an ultra-conservative course often assumes unwarrantable responsibilities in attempting to guard against subsequent troubles which more radical procedures might have successfully averted.

His conclusions as to ultimate results are based on a palpably wrong assumption that the primary wound is aseptic. Such a condition is, however, so exceptional that it may be regarded as the merest accident. Not only the bullet itself may be infected, but portions of clothing which are so often carried with it are quite likely to be. Even if the latter is not the case, woollen and other fragments never become enveloped in protecting tissue, and always serve to maintain an open sinus which constantly invites direct infection.

The size of these foreign substances has nothing whatever to do with the degree of wound poisoning which may result from their presence in vital tissues. Oftentimes the smaller the splinter of bone, for instance, or the more diminutive the portion of clothing, the greater the damage, as such disturbing elements are often invisible even to the radiograph, and their existence is frequently unsuspected. All this is the strongest possible argument for a wound that can be guaranteed to be perfectly aseptic from the start by the primary and absolute removal of every suspected influence to the contrary.

The comparatively simple character of the original injury, while it might give the best possible reasons for making assurance doubly sure in eliminating all chances of future trouble, is of itself no indication that the ultimate results of possible complications may not be out of all proportion to ordinary expectations. If the wound tract is septic in the slightest degree, there is no end of the trouble which may result to the neighboring tissues by burrowing abscesses, erosion of bone from pressure, and contiguous infection by the formation of inaccessible pus pouches, together with the other preliminaries of an inevitable pyæmia. This was illustrated in the melancholy case of President Garfield, wherein the ultimate results of widespread suppuration and constant pus-soakage of the spongy portion of the perforated vertebra were clearly and painfully apparent. The danger of the latter condition was never before more pointedly demonstrated, nor more clearly proven to be beyond remedy when once established, than by the autopsical relations of cause and effect. The possibility in Labori's wound of the bullet opening an infected track in the substance of the wounded dorsal vertebra is certainly not beyond reasonable calculation so long as the ball is allowed to remain where it is. While very often it requires a great deal more courage to advise against an operation than to perform it, it is nevertheless equally true that when a radical procedure can be adopted which promises immunity from subsequent dangers with a minimum risk, it is a fortunate circumstance for the surgeon when succeeding events prove that he has not erred in making an exception to a general and accepted rule of action. From such a point of view the profession will watch the outcome of this now famous case with more than ordinary interest.

## THE OPERATIVE CURE OF ASCITES DUE TO CIRRHOSIS OF THE LIVER.

ONE must often attempt to relieve symptoms when hope of cure is out of the question. There are no known remedies that are capable to any notable degree of restraining the progress of cirrhosis of the liver when once begun; but it has been shown that relief from one of the most troublesome symptoms of this disorder can be afforded by surgical operation directed to the esablishment of an adequate collateral circulation for the omental and peritoneal vessels. Cases in which such a result was thus secured have been reported by Drummond and Morison (*British*

*Medical Journal*, September 19, 1896), and one has also been reported by Weir in the MEDICAL RECORD for February 4, 1899. Further evidence, both clinical and pathological, of the successful accomplishment of the object in view is presented in a recent communication by Morison (*The Lancet*, May 27, 1899), who reports the case of a man forty-two years old, who presented himself on account of abdominal distention of rapid development.

The patient had had three attacks of left-sided pneumonia, and was accustomed to take not more than a pint of beer at dinner and supper, and occasionally a glass of whiskey. On examination signs of a large collection of free fluid in the abdomen were found present, while the liver dulness could not be distinguished, and the spleen was so much enlarged as to fill the left iliocostal and lumbar spaces and to bulge forward the left flank. The abdomen was opened midway between the umbilicus and the ensiform cartilage for exploratory purposes, and the liver was found to be hard, hobnailed, and somewhat diminished in size, and the spleen enlarged to at least six times the normal. A second incision was made three inches above the pubes, and a glass drain introduced into the recto-vesical pouch. About three gallons of fluid escaped through the upper opening and through the tube. After emptying the peritoneal cavity and drying it with sponges, the anterior surface of the liver, the outer surface of the spleen, the exposed coils of intestines, and the parietal peritoneum were all firmly sponged, and the omentum was attached by sutures widely to the parietal peritoneum lining the anterior abdominal wall. The whole of the upper wound was closed by deep and superficial sutures, and the glass drainage tube was left projecting and firmly gripped below. The further surgical course of the case was uncomplicated, but the patient became much depressed mentally, although he was in good health two years after the operation.

A patient who had been previously operated on for ascites complicating cirrhosis of the liver, developed after two years a ventral hernia, which became aggravated by cough, and she sought operation for its relief. The woman recovered from the immediate effects of the operation, but in a short while she became restless and complained of pricking pains and numbness in the arms and legs. On the following morning, after a restless night, the patient was distinctly jaundiced and complained still more of the numbness and pain. Jaundice and restlessness increased, and on the second day after the operation the woman became comatose and died, deeply jaundiced. At the autopsy the whole of the abdominal viscera and the parietes excepting the skin were removed *en masse*, and the vessels injected from the trunk of the portal vein. The liver, the spleen, and the intestines were attached to the parietes, chiefly by numerous band-like adhesions, many of which seemed each to contain little except a blood-vessel, which in several was four inches in length. The omentum also was firmly adherent to the anterior abdominal wall by strong bands, and in all of these adhesions innumerable injected vessels could be readily seen passing from the omentum and viscera through the parietes. Many of these vessels were as large as a normal radial artery. The subperitoneal plexus of vessels formed a dense large network.

As a result of his experience in these cases, Morison reaches the conclusion that (1) ascites due to cirrhosis of the liver can be cured by the establishment of an efficient anastomotic circulation. (2) Adhesive peritonitis produces adhesions between the abdominal contents and its parietes in which new blood-vessels form. If there is any demand for these vessels they remain permanently. (3) The operation described seems to be the safest and most certain method of producing adhesions. (4) It is no longer advisable to treat the ascites due to cirrhosis of the liver by repeated tappings if the patient is otherwise sound and in fair general condition. After one or two tappings have failed, operation offers the best chance of prolonged and useful life.

## THE PHYSICAL DEVELOPMENT OF JAPANESE WRESTLERS.

ALTHOUGH the American is willing to concede to the Japanese the possession of a mental capacity almost if not quite equalling that of the majority of white races, he is apt to form a somewhat slighting opinion of him as viewed from a physical standpoint. The specimens met with in this country do not tend to convey a favorable impression of their athletic powers. After, however, reading an account of the physical measurements of some of the most prominent Japanese wrestlers, a more respectful attitude regarding the muscular development of these little men will probably be taken. The *Jiji Shimpo* has recently published a table giving the measurements of six of the foremost Japanese fighters. From this table it is gathered that the most bulky of these modern gladiators weighs at the age of twenty-two years about three hundred pounds; height, five and a half feet; girth of chest, fifty-eight inches, lung capacity, four thousand four hundred and fifty cubic centimetres; upper arm, eighteen inches. Another one weighs over two hundred and eighty pounds; height, six feet five inches, girth of chest, forty-eight inches; lung capacity six thousand cubic centimetres; upper arm, sixteen inches. The smallest of these fighting men weighs more than two hundred pounds, measures in height five feet seven inches, while in lung capacity he exceeds them all. There are few wrestlers or pugilists in this or any country who attain to these dimensions, and those who have seen some of the best exponents of Japanese wrestling are willing to back them when pitted against the pick of the European or American experts, as it is said that they are as skilful as they are powerful.

**Gift of an Ambulance.**—A lady resident in Sing Sing, whose name is withheld at her own request, has presented through Dr. W. A. Miner an ambulance with all its equipment to the Ossining Hospital of that place. It is patterned after those in use in Central Park, in this city.

## THE ETHICS OF CONSULTATION IN THE LABORI CASE.

It is a deplorable fact that almost every medical or surgical case which in consequence of the position or importance of the patient is the subject of newspaper comment has its dark background of additional sensation in the shape of a professional scandal of some sort. There is seemingly a craze for notoriety on the part of some of the outsiders which focusses its venom of envy on those who are doing their best to perform strictly professional duties in a difficult and responsible case. The latest manifestation of this propensity has been evident in the full and disgusting public ventilation of the unseemly surgical quarrel over the particular treatment which Laborı should receive. The aggravation of the wrong from an ethical standpoint is the assumption of right on the part of a friend of the patient, also a surgeon, to make an unsolicited professional visit, apparently on the ground of personal concern for the sufferer, and force his professional advice upon the gentleman in charge of the case. As is quite natural under the circumstances, the regular surgical attendant resents the unwarranted interference with his vested rights, and a stormy interview follows, in which sarcasm, innuendo, and insult have the freest possible interchange. No more typical doctors' quarrel founded on radical disagreement as to respective privileges could have found its way into the history of any public scandal. In the course of the pardonably animated protest of the real surgical attendant it was openly charged that the volunteer consultant was rather carelessly throwing himself in the way of extensive newspaper notoriety, an opinion which was abundantly substantiated by subsequent events.

## News of the Week.

**The Pasteur Institute.** — The annual report published by the *Annales de l'Institut Pasteur* states that during the past year, 1898, 1,465 persons underwent treatment, of whom 4 only died. Of the 1,465 persons inoculated 141 had been bitten by persons experimentally proved to be mad, 855 by animals declared to be mad, and 469 by animals suspected of being so. With regard to nationality 1,353 were French and 132 foreigners, the latter consisting of 56 from British India, 25 from England, 21 from Switzerland, 3 from Greece, 2 from Egypt, and one each from Spain, Turkey, and Austria, other countries, notably Italy and Russia, having institutes of their own.

**The Independence of the University of Berlin.**— The German Government has made persistent attempts to secure the dismissal of Dr. Leo Arons, a privatdocent in electricity at the University of Berlin, for the reason that he is a Social Democrat in politics. The faculty of the university has recently formally tried the accused, but as no instances of improper teaching were shown, the arguments turned solely on the right or wrong of Social Democracy. The Berlin University decided that the fact that an instructor belongs to the Social Democratic party was no reason for his dismissal, and, though an appeal has been taken to the minister of education, the faculty of the university still stands by its member.

**The New York Society for the Prevention of Cruelty to Animals** removed last year from the streets of this city 25,466 diseased, starving, and homeless dogs and 62,474 cats. Of these 1,511 lost dogs were restored to their owners; the others were killed by immersion in illuminating-gas. The lost animals are kept forty-eight hours, awaiting possible identification by their owners, and those unclaimed after that time are destroyed.

**Yellow Fever** is reported to be spreading rapidly at Tuxpan, Mexico, fifty deaths having occurred since the beginning of the outbreak. The Marine-Hospital service has been notified of the appearance of a case of the disease at Port Lima, Costa Rica. One of the United States marines stationed at Havana has died at the naval hospital there of yellow fever, and the entire marine battalion, consisting of forty men, has been sent north. The men arrived at this port a few days ago, without impediments of any kind, and were quarantined to await the expiration of the usual period of incubation.

**Too Much Chicago.**—The editor of *The Illinois Medical Journal*, the official organ of the Illinois State Medical Society, in commenting upon the programme for the semi-centennial meeting to be held in Springfield in 1900, says that it "should not contain the names of too many Chicago men. Of course every man in Illinois believes in Chicago, but it is not the entire State. The medical men in Chicago have ample opportunity to disport their knowledge. Some of them do not hesitate to do so, almost *ad infinitum* and in some instances *ad nauseam*. They should curb their impetuosity when away from home. They should let the others have a chance. Strange as it may seem, they may learn something if they are attentive."

**Service in the Hospital Corps.**—An effort is being made to secure as many enlistments as possible of qualified men for the army hospital corps. Service in the hospital corps is considered desirable because of the higher pay as well as of the class of work to be done. The corps consists of stewards, acting stewards, and privates, who receive $45, $25, and $18 a month respectively, with twenty per cent. added in time of war. The private of the line receives about $13, with the same percentage of increase in time of war; and even the sergeant-major of a regiment is paid about $10 less a month than a hospital steward.

**Calomel and Lemon Juice for Snake Bites.**—A certain Dr. Corillano Dutra, of the state of Matto Grosso, Brazil, has sent a sworn statement to the Academy of Medicine of Rio de Janeiro affirming that he cures persons bitten by any of the venomous reptiles of Brazil, by means of thirty grains of calomel and one ounce of lemon juice, repeated every two hours until three doses have been taken. He claims

to have effected cures by this remedy even when the patient was seemingly moribund. The credence which might be accorded, with reservations, to this statement is somewhat rudely shaken, however, by a further assertion by the same Dr. Dutra. He says that a few grams of corrosive sublimate tied to some part of the body will prevent any snake from biting the person thus guarded, and if the snake should be followed up and forced to bite, the bite will be innocuous.

**Liberal Bequest.**—By the will of the late Benjamin D. Masham of Vineland, N. J., the sum of $100,000 is devised to the New Jersey Training-School for Feeble-minded Children on the death of his widow.

**High-Altitude Insanity.**—A man from Wisconsin, accused of attempting to poison a resident of Colorado Springs, has been acquitted on the plea of insanity, several physicians testifying that his insanity was due to the high altitude of the town.

**Condemnation of Animal Suspects.**—The board of health of Altoona, Pa., has ordered all stray cats, dogs, and other pet animals to be killed. This action is taken because those animals are suspected of assisting in the spread of smallpox in the city.

**Punishment of Rebellious Students.**—In consequence of the student insurrection which occurred in all the Russian universities, except those in Finland, last year, it has been decided by the government that hereafter any university or high-school student who creates or instigates disorders shall be forcibly drafted into the Russian army, and compelled to render from one to three years' service.

**Antivaccinationists in England.**—The Leicester Guardians, consisting of thirty-five men and five women who were elected under a pledge to oppose in every possible way the enforcement of compulsory vaccination, were recently brought into court for refusing to appoint a vaccination officer as the law provides. The court mandamused them to compel them to appoint a public vaccinator, and the "martyrs" returned from London to Leicester cheered on their way at every station by the plaudits of enthusiastic but indignant sympathizers.

**Medical Education in Kentucky.**—The State board of health of Kentucky has issued a circular giving notice that it will hereafter refuse to recognize, as a basis for certificates to practise medicine, diplomas from any medical college which does not, in good faith, comply with the requirements of the American Medical College Association, the American Institute of Homœopathy, and the American Eclectic Medical College Association, respectively, as to both preliminary education and a four years' course of study. This means that no school that graduates three-year students will be recognized in this State hereafter. The board provided an examination for three-year graduates of the present year, as many students had attended such schools in ignorance of the advanced requirements, but the result was unsatisfactory, a large number of the examinations indicating incomplete preliminary education as well as imperfect medical training. This standard for the State of Kentucky was made and promulgated in 1891, to take effect this year.

**A New Sterilizer.**—A new preparation composed of chlorate of potash and sulphuric acid has been introduced by Professor Bergé, of Brussels University. He claims for it that when brought into contact with water the chloric acid of the mixture becomes decomposed into oxygen and what he calls "poleozone," which he says is the most energetic oxidizing agent and bactericide known. Fishes and plants, he alleges, live well in water impregnated therewith, but it at once destroys all microbic life.—*The Medical Press and Circular.*

**The Yellow-Fever Germ.**—According to press despatches from Washington, the bacteriologists of the Army Medical Museum do not accept the conclusions of the Marine-Hospital commission, published in these columns last week, regarding the Sanarelli bacillus. These despatches quote Surgeon-General Sternberg as saying that "Drs. Reed and Carroll are now preparing a report of their extended researches, which have been going on in the Army Medical Museum during the past two years. This report will be published in due time, and will give full details of the experimental evidence upon which they base their conclusion that Sanarelli's bacillus is a variety of the bacillus of hog cholera. It appears to me at the present time that, like the colon bacillus and bacillus X, the bacillus of Sanarelli is present occasionally and accidentally in yellow-fever patients, and that its etiological relation to this disease has not been established."

**The Italian Society of Internal Medicine** will meet in tenth annual session in Rome on October 23d to 26th, under the presidency of Dr. Guido Baccelli. The subjects of the set discussions are chlorosis and the pathology of the pancreas. There will also be reports on the progress during the year of therapeutics and diagnosis by Drs. Boeri and Riva Rocci. Foreigners who wish to make application for associate's tickets (10 lire) may address Prof. L. Lucatello, 5, Via Università, Padua.

**Marriage of the Subjects of Venereal Disease Forbidden.**—A law recently passed by the Michigan legislature forbids the marriage of any person suffering from gonorrhœa or syphilis, and provides that any one so diseased who may marry shall be guilty of a felony punishable by a fine of not less than $500 or more than $1,000, or imprisonment in the penitentiary for a term not exceeding five years, or by both fine and imprisonment. A wife or husband may testify against her or his guilty spouse, and the privilege of medical secrecy is also abrogated in such cases.

**Food Inspection in Philadelphia.**—The subject of food adulteration was brought to the attention of the July grand jury at Philadelphia, which made a special presentment on the subject, saying that "the adulteration of food is a matter of such vital importance to

every member of the community that the strongest measures should be taken to prevent and punish the crime." Special attention was called to the fact that it is not always the retailer who is at fault, but that very frequently the adulteration is made by the wholesaler or manufacturer. The Pennsylvania law prohibits the use of borax, boracic acid, salicylate of sodium, and salicylic acid as preservatives in any article of food, and this provision of the adulteration act is relied upon in many instances to secure convictions, these preservatives being frequently used by milk dealers. The Pennsylvania oleomargarine law is also quite severe, the retail dealer being held responsible even if he himself bought oleomargarine in the belief that it was butter.

**Typhoid Fever in an Almshouse.**—A number of cases of typhoid fever have occurred in the Warren County (N. J.) almshouse, several of the nurses and other officials and some of the inmates having been attacked. The number of persons in the institution is quite large, and heretofore the general health has been very good.

**The International Congress of Dermatology and Syphilography,** which has its own permanent organization, has for the next meeting united with the Thirteenth International Congress of Medicine, of which it will form an independent section in Class II.

The work of the congress in dermatology will be comprised in four discussions, as follows:

1. Parasitic Origin of Eczemas—By Kaposi of Vienna, Unna of Hamburg, Jadassohn of Berne, J. Galloway of London, Brocq of Paris, assisted by Bodin of Rennes and Veillon of Paris.

2. Tuberculides—By Boeck of Christiania, Colcott Fox of London, Campana of Rome, G. Riehl of Leipsic, and Darier of Paris.

3. Alopecia—By Malcolm Morris of London, Lassar of Berlin, Mibelli of Parma, Pavloff of St. Petersburg, and Sabouraud of Paris.

4. Leucoplasia—By Behrend of Berlin, J. J. Pringle of London, and Perrin of Marseilles.

In syphilography the discussions will be:

1. Syphilis and Associate Infections—By Neisser of Breslau, L. D. Bulkley of New York, Ducrey of Pisa, and Hallopeau of Paris.

2. Hereditary Syphilis—By J. Hutchinson of London, Tarnowsky of St. Petersburg, Finger of Vienna, and L. Jullien of Paris.

3. Causes of Generalized Infections in Blenorrhagia—By Taylor of New York, Lassar of Berlin, Tommasoli of Palermo, J. E. Lane of London, and Balzer of Paris.

**Prosecution of an Illegal Practitioner.**—Dr. (?) A. M. Petrella, of Brooklyn, was arrested recently for the second time for alleged illegal practice of medicine. He is an Italian, who came to this country a year ago and settled in Brooklyn, displaying a sign on his house with his name and the letters M.D. He had no license from the State board of examiners, nor was he registered, and was arrested for illegal practice. For some reason he was acquitted, but was warned not to practise medicine without being properly registered. He did not get registered, and was arrested again a few days ago on the complaint of a dissatisfied patient. His plea was that, being a graduate of the University of Naples, he should be permitted to practise here without submitting to another examination.

**Foot-and-Mouth Disease** prevails in Egypt, a recent statement placing the number of cases of the disease reported for the month ending August 15th at eighteen hundred and twenty-seven.

**The American Pharmaceutical Association** will meet on September 4th and the following days at Put-in Bay, Ohio. The association is reported to have a membership of about eighteen hundred.

**The "Epidemic" of Infantile Paralysis** at Poughkeepsie has subsided. One of the cases, that of a boy about five years old, resulted fatally, and a section of the spinal cord is to be examined in order to determine the true nature of the disease.

**Dr. John McG. Woodbury** of this city, now a surgeon in the United States army, has been assigned to witness the manœuvres of the sixth German army corps at Silesia on September 23d, and to report upon the practical operation of the German military medical service.

**Smallpox in Texas.**—As a result of the bad sanitary condition, following the recent disastrous floods in the Brazos valley, an epidemic of smallpox has broken out. Many negroes in Bastrop, Brazos, Robertson, and other counties are down with the disease. The State board of health has taken charge of the situation.

**A New Hospital Building.**—The Beth Israel Hospital Association filed plans with the building department of this city recently for a six-story and basement brick fireproof hospital building, to be erected on the northwest corner of Jefferson and Cherry streets. The building will be one hundred and seventy-eight feet in ground area, and its estimated cost will be $100,000.

**Mosquitos and Malaria.**—Major Ross, the discoverer of the life cycle of the proteosoma of birds in the gray mosquito, and the head of the expedition sent out by the Liverpool School of Tropical Diseases to study malaria in Sierra Leone, has sent a despatch to Liverpool announcing the discovery of the special mosquito concerned in the dissemination of malaria in that region. He asks that the British government send a scientific force to work in conjunction with him.

**Uniform for Army Nurses.**—The new uniform for United States army women nurses, according to instructions recently issued by Dr. Anita McGee, assistant surgeon U. S. A., will consist of a waist, with adjustable cuffs, and an apron of white linen, worn with a skirt and necktie of army blue galatea. A jacket of the galatea style is also provided, to be worn when desired. Caps are not to be used. Chief nurses are entitled to wear, in place of the apron, a sash of red silk, knotted around the waist. Each nurse may have

the uniform made as best suits her convenience, but the material and cut are to be as prescribed. The badge of the nurses' corps will be a special form of a Greek cross of dark enamel, edged with gold.

**The Plague** is apparently spreading gradually in various directions, Europe being threatened from several sides. At Oporto forty-nine cases occurred between June 4th and August 21st, of which number sixteen terminated fatally. The government has decided to isolate the city by means of a sanitary cordon. Dr. Jorge, the director of the Bacteriological Institute at Oporto, has become the object of popular disapproval because he had the courage to assert that the plague existed in the city when the authorities wished to conceal its presence. A mob gathered near his house and was dispersed only by active efforts of the police, and he was also assaulted by a member of the Chamber of Deputies. The disease was brought to Oporto from India on a ship loaded with rice. It is reported that several cases of plague have occurred at Palermo and at Naples, and it is also believed to have broken out in the government of Samara in Russia. Several cases of suspected plague have occurred at Magude, a short distance from Lourenzo Marquez, Delagoa Bay. There is little danger of the disease being brought to this port from Oporto by immigrants or in cargo, but if it is true that rats are active in the spread of the disease, there would probably be some danger in allowing a vessel from an infected port to dock here, even if there were no cases of the disease among either passengers or crew at the time of arrival.

**Navy Department,** Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending August 19, 1899. August 15th.—Assistant Surgeon F. R. Bogan detached from the *Wabash* and ordered to the *Scorpion*. Assistant Surgeons G. D. Costigan, M. S. Elliott, F. L. Pleadwell, D. N. Carpenter, D. S. Morgan, J. C. Pryor, promoted to the rank of lieutenants, junior grade, from July 1, 1899. August 17th.—Surgeon L. B. Baldwin ordered to be examined by the naval retiring-board, Washington, D. C., September 12th, and then home and to wait orders. Surgeon L. W. Atlee detached from the *Bennington* and ordered to the *Solace*. Passed Assistant Surgeon H. D. Wilson detached from the *Castine* and ordered to the *Solace*. Assistant Surgeon W. M. Wheeler detached from the *Baltimore* and ordered to the *Solace*. Assistant Surgeon J. C. Thompson detached from the *Baltimore* and ordered to the *Castine*. Assistant Surgeon D. G. Beebe detached from the *Monadnock* and ordered to the *Bennington*. Assistant Surgeon T. M. Lippitt detached from the *Solace* and ordered to the *Baltimore*. Assistant Surgeon F. M. Furlong detached from the *Solace* and ordered to the *Oregon*.

**Death of Prof. von Bunsen.**—Robert Wilhelm Eberhard v. Bunsen, the famous chemist, died at Heidelberg on August 16th. He was born at Göttingen on March 31, 1811, and took the degree of doctor of philosophy at the university there in 1830. He afterward studied in Berlin, Vienna, and Paris. In 1852 he was appointed professor of chemistry at Heidelberg, which place he held until he died, although he had not lectured for some time. Although a chemist, it was in physics that his greatest discovery (that of spectrum analysis) and inventions (the Bunsen burner, the Bunsen pump, the Bunsen battery, and the spectroscope) were made. In 1883 he was elected one of the eight foreign associates of the French Academy of Sciences.

**Obituary Notes.**—Dr. Samuel B. McLeod, of this city, died after a brief illness, on August 23d. He was born in New York in 1831 and was graduated in arts from the University of Pennsylvania, and in medicine from the College of Physicians and Surgeons, Medical Department of Columbia College, in the class of 1852. After a year spent in study abroad Dr. McLeod entered the United States navy, serving as assistant surgeon. He resigned at the end of two or three years and began practice in this city. He was a prominent member of the New York County Medical Association and was for five years its president. He was also for one term president of the New York State Medical Association and of the Medico-Legal Society. He was consulting physician and surgeon to the New York Lying-in Asylum and consulting physician to the Northern Dispensary, and was also formerly a surgeon of police. He is survived by a widow and two sons, one of the latter a practising physician.—Dr. William D. Hartmann died at West Chester, Pa., on August 16th, at the age of eighty-one years. He was graduated from the medical department of the University of Pennsylvania in 1839, and continued in practice almost up to the time of his death. He was a recognized authority in the natural sciences, especially conchology, entomology, geology, and mineralogy, and his collection of shells was especially rich in the genera of partula and achinella.—Dr. William A. Jacobs died at Centre Hall, Pa., of pneumonia, on August 16th. He was a graduate of the medical department of the University of Pennsylvania in 1875. He had previously served in the Civil War as second lieutenant of Company G, One Hundred and Forty-eighth Pennsylvania Volunteers. He was for six years a member of the Centre County pension examining-board.—Dr. Alexander Craig died in an apoplectic attack at Columbia, Pa., on August 17th, at the age of sixty-one years. He was graduated from Jefferson Medical College in 1865, and was for thirty years surgeon to the Pennsylvania Railroad Company.—Dr. J. Pembroke Thom, of Baltimore, died in that city on August 21st, after an illness of several months, at the age of seventy-one years. As a young man he entered the United States army, serving in the Mexican War. He afterward took up the study of medicine, was graduated from Jefferson Medical College in 1851, and entered the medical service of the navy. He entered the Confederate army at the breaking out of the Civil War, but resumed the practice of medicine in Baltimore at its close. He was speaker of the Maryland House of Delegates in 1884.

# Reviews and Notices.

La Guerre Gréco-Turque: Résumé historique et stratégique, accompagné de Notes médicales et largement illustré. Par Dr. Edmond Lardy, Chef d'Ambulance de la Banque Impériale Ottoman en Thessalie, etc. Neuchatel: Attinger Frères. 1899.

This is an historical and statisticai account of the Greco-Turkish war, written by a surgeon who was with the Turkish army in a semi-official capacity. The military and geographical parts of the book are of considerable interest, much more than the medical, which is simply a series of short clinical histories of some of the cases seen by the author.

Retinoscopy (or Shadow Test) in the Determination of Refraction at One Metre Distance, with the Plane Mirror. By James Thorington, M.D., Adjunct Professor of Diseases of the Eye in the Philadelphia Polyclinic and College for Graduates in Medicine. Third edition, revised and enlarged. Forty-three illustrations, twelve of which are colored. Philadelphia: P. Blakiston's Son & Co. 1899.

This well and tersely written little work of eighty-six pages gives evidence of its popularity by having reached its third edition in about two years. The text is well illustrated, it contains nothing that is superfluous, and is devoid of abstruse formulæ. The author's personality is much in evidence, but this does not detract from the value of the work. The volume is intended for college students and post-graduates, and for these it is certainly most excellently adapted.

Defective Eyesight, The Principles of its Relief by Glasses. By D. B. St. John Roosa, M.D., LL.D., Professor Emeritus of Diseases of the Eye, New York Post-Graduate Medical School and Hospital; Surgeon to the Manhattan Eye and Ear Hospital. New York: The Macmillan Co. 1899.

This little work of one hundred and ninety-six pages is devoted to an explanation of the uses of eye-glasses, and why they are of value to many persons, and to a description of some of the methods employed in determining the glasses suitable for the individual case. It is written in a semi-popular vein, the author having designed it for the use of "the student and practitioner in ophthalmology," also for "those educated people, who having a special interest in the subject, wish to know the principles on which the prescription of glasses is based." A number of historical paragraphs embellish the pages of the book. Quite an extensive description of how to use the ophthalmometer of Javal and Schiotz is found, and also an exposition of the author's well-known views on asthenopia. Retinoscopy is not mentioned. The work will perhaps be read with interest, especially by those who are more or less conversant with the author's previous writings on kindred subjects, but we doubt whether there is any long-felt want which it can fill. Like most of its class, it teaches too little for those who want to know much, and too much for those who need to know but little.

Atlas of the External Diseases of the Eye, including a Brief Treatise of the Pathology and Treatment. By Prof. Dr. O. Haab, of Zurich. Authorized translation from the German; edited by G. E. de Schweinitz, A.M., M.D., Professor of Ophthalmology in the Jefferson Medical College, Philadelphia. With seventy-six colored plates and six engravings. Philadelphia: W. B. Saunders. 1899.

This volume of two hundred and twenty-eight pages forms an excellent companion book to Professor Haab's "Atlas of Ophthalmoscopy." The first seventy-eight pages are devoted to an explanation of the methods of examining the eye, which are given in minute detail. Diseases of the lacrymal apparatus, eyelids, conjunctiva and cornea, sclera, iris and ciliary body, lens, vitreous body, globe, and orbit are described, and the etiology, diagnosis, and treatment given. All are quite fully and beautifully illustrated by forty lithographic plates and six figures in the text. The drawing and coloring of the plates are excellent, and they are with very few exceptions remarkably true to nature. The only thing that could be objected to in the work is the apparent attempt to do justice to a large subject in a small volume. The work is excellently suited to the student of ophthalmology and to the practising physician. The enviable status of the author and of the editor, in the field of ophthalmology, guarantees the excellence of the work. It cannot fail to attain a well-deserved popularity. The moderate price puts it within the reach of all.

Su di un Nuovo Metodo di Autoftalmoscopia, Per il Dott. Pedro de Obarrio. Traduzione del Dott. A. Neuschuler. Pavia, 1899.

The autophthalmoscopy described in this short pamphlet consists in so arranging a lighted candle in a darkened room that, by means of a small plate of glass with parallel surfaces properly manipulated, the observer may bring into view the image of the light as formed on his own retina, with false projection into space.

New York Eye and Ear Infirmary Reports. Vol. VIII. New York: The Knickerbocker Press. January, 1899.

This journal, which aids to individualize the work done at the institution from which it emanates, contains twelve articles by as many members of the surgical staff and a brief summary of the hospital statistics. The departments of ophthalmology, otology, and laryngology are represented.

A Practical Handbook on the Muscular Anomalies of the Eye. By Howard F. Hansell, A.M., M.D., Clinical Professor of Ophthalmology, Jefferson Medical College; Professor of Diseases of the Eye, Philadelphia Polyclinic and College for Graduates in Medicine; and Wendell Reber, M.D., Instructor in Ophthalmology, Philadelphia Polyclinic and College for Graduates in Medicine. With 28 illustrations and one plate. Philadelphia: P. Blakiston's Son & Co. 1899.

This volume of one hundred and eighty-two pages is devoted principally to a discussion of the functional anomalies of the eye muscles. The text is divided into four parts: Part I., Anatomy and Physiology of the Extrinsic Muscles of the Eye; Part II., Ocular Palsies; Part III., Heterophoria and Heterotropia; Part IV., Operations on the Eye Muscles. The book is designed for the use of beginners in ophthalmic work, but it is well worthy of perusal by all who are interested in the subject of anomalies of the muscles of the eye. The consideration of the subjects treated of in Parts I., II., IV., and in the second chapter of Part III., is brief, but clear and concise. The chapter on heterophoria gives evidence of a careful study of the subject, and expresses conclusions arrived at by personal experience in the treatment of this condition. Methods of diagnosis and of the treatment of the various anomalies are quite fully discussed, and values of all are given without the bias of the hobbyist. The work is a valuable contribution to this branch of ophthalmology.

An Experimental Research into Surgical Shock: An Essay Awarded the Cartwright Prize for 1897. By George W. Crile, M.D., Ph.D., etc. Philadelphia: J. B. Lippincott & Co. 1899.

We have in this volume a description of an extended series of experiments and the author's conclusions on the phenomena of surgical shock. The experiments are described in detail, with many diagrams to explain various conditions of blood-pressure, pulse, respiration, and other physiological factors. To the average reader the most important parts of the essay are the conclusions. The author believes that surgical shock is due to a vasomotor breakdown or impairment, and that there are several extraneous conditions which contribute to its development. Hemorrhage is of great importance; temperature, posture, and the region of the body operated upon, are also to be considered. These experiments have shown that chloroform is much more apt to kill than ether, and that animals will die under the continuous administration of an anæsthetic, when it is merely given to the surgical degree. The region of the body operated upon does not appear to make much difference in reference to shock, except that in general shock increases as we approach the diaphragm, and that in the region of the gall-bladder and pylorus it seems to be especially marked. The male genitals offer an exception to this rule, for injuries to them cause severe shock. The author's treatment for shock is posture, saline infusion, and the use of small repeated doses of strychnine subcutaneously, with other subsidiary measures.

# Society Reports.

## INTERNATIONAL CONGRESS OF GYNÆCOLOGY AND OBSTETRICS.

*Held in Amsterdam, August 8, 9, 10, 11, and 12, 1899.*

(Special Report to the MEDICAL RECORD.)

*First Day—Tuesday, August 8th.*

**The Opening Ceremonies** took place at 3 P.M. in the aula of the university, and were of a general nature.

PROFESSOR TREUB, the president, delivered the inaugural address, which was, in the main, a welcome to the various members and delegates, with a short reference to the field of work proposed.

DR. MENDES DE LEON, general secretary of the committee of organization, followed in somewhat the same strain. He announced that the number of members present at the congress was, so far, one hundred and fifty-five. Also that an invitation had been received from the British Gynæcological Society to hold the next international congress, 1902, in London. The various delegates then, in turn, expressed the thanks and conveyed the greetings of the countries they represented. In the evening an official reception was tendered the members of the congress by the municipal council at the Hôtel de Ville.

---

*Second Day—Wednesday, August 9th.*

**An Instrument for Developing the Breasts.**—DR. MENSINGA, of Flensburg, demonstrated a new instrument devised for the treatment of undeveloped mammæ. Its principle was that of massage by means of the frequently repeated slight pressure of an ivory knob, fastened, like a dentist's curette (or hammer for putting in gold filling), to a sort of dental machine.

**Shortening of the Broad and Round Ligaments in Retroversion.**—M. DELAGENIÈRE, of Le Mans, read a paper with the above title. He remarked that in the operative treatment of retroversion these operations should be regarded as auxiliary to others, such as salpingo-oöphorectomy, or colpo-perineorrhaphy. If the retroversion was reducible, the operation of choice should be extraperitoneal; if irreducible, intraperitoneal. In the extraperitoneal operation, the uterus should be curetted; the cervix amputated, if necessary; the uterine arteries tied, if the organ was enlarged or there were small fibromata; repair of the vagina; a perineorrhaphy or a colpo-perineorrhaphy; and finally, Alexander's operation. The intraperitoneal operation should remove adhesions, treat lesions of the adnexa, and finally correct retroversion by shortening the broad or the round ligaments. Only the round ligaments should be shortened when there was no prolapse; but when the uterus seemed to be sunk in the pelvis, the broad should be shortened. He reported a personal experience of thirty-three operations, of which fifteen were extra- and eighteen intraperitoneal. In the extraperitoneal operations Alexander's operation and curetting were done in all; in fourteen the cervix was amputated; in eleven perineorrhaphy, in two anterior colporrhaphy, and in two ligature of the uterine arteries were done. In the intraperitoneal, the broad ligaments were shortened in nine, and the round in nine. In all, the adnexa were removed on both sides. Immediate results were excellent in all; the remote results were good in all that he had since seen.

DR. JACOBS, of Brussels, said that in three of his cases pregnancy had occurred, and had been normal; after involution the uterus had returned to the corrected position.

DR. C. A. L. REED, of Cincinnati, said that abdominal section, which for shortening the broad ligaments was in any case necessary, was also his operation of choice for the round ligaments, because in nearly all cases there were accompanying lesions of the adnexa which needed treatment by the abdominal route. His results were very satisfactory. He declared himself against the various fixation operations. The only method which had stood the test of experience in securing permanent anteversion was Alexander's.

DR. VINEBERG, of New York, had, in order to shorten the round ligaments, devised an anterior vaginal incision, through which the uterus could be brought out. In forty operations the uterus had remained forward permanently, except in two or three cases. Four subsequent pregnancies had been normal. The advantages of this over Alexander's operation were: less pain subsequently; no external scar; no danger of hernia; possibility of a good inspection of adnexa.

DR. ALEXANDER, of Liverpool, said he reserved his operation for cases in which the uterus could be brought forward easily by sound or finger. Failures were probably due to not pulling out the ligament far enough.

**Treatment of Fistulæ, Post-Operative and Spontaneous, in Gynæcology.**—DR. DOYEN explained at some length an operation devised by him for various fistulæ. The description of this operation was too long and complicated to be given in this report.

**Demonstration of a Forceps for Intestinal Anastomosis.**—DR. LAPLACE, of Philadelphia, demonstrated the forceps lately devised by him for this purpose.

**Total Abdominal Hysterectomy in Uterine Cancer.**—DR. REYNIER, of Paris, read a paper with the above title. This operation (formerly recommended by Freund) permitted, he argued, a more thorough inspection and removal of lesion than the vaginal route. In particular, the vaginal mucosa could be more extensively and surely removed. The limits of the operation, as in cancer elsewhere, were very definite. Infiltration of the bladder or rectal wall was a contraindication. The prognosis was good if the broad ligament was only slightly involved. He advised prophylactic saline injections twenty-four to forty-eight hours before operation, the general condition being usually poor. In the operation, he began by marking out his lower incision in the vaginal wall. In the broad ligament, when he had to leave cancerous tissue in too extensive cases, he left on forceps *à demeure*, believing that there was thus less danger from secondary hemorrhage than in the employment of the ligature or of the angiotribe. In other points his operation offered nothing unusual.

DR. DOYEN, of Paris, thought that Dr. Reynier had operated cases too far advanced. If the glands or the broad ligaments were much involved, operation was contraindicated. The possibility of complete removal was the only justification for operations for cancer.

DR. JACOBS, of Brussels, agreed that the abdominal route was the only proper one for a radical operation. It was necessary to clean out the pelvis in all cases, and to dissect away all lymphatic and cellular tissue very widely. His first ten cases were followed by rapid recurrence. A second series of twenty-three cases, better selected, had resulted in twenty-two cures without recurrence so far, but with one death from infection. These had all been done in the past one and one-half years, too short a period to estimate the curative value of the operation. But as in eighty-one cases done per vaginam there had been forty-

three recurrences within one year, he considered the abdominal route a great improvement.

Dr. Jonnesco, of Bucharest, remarked that cleaning out of the pelvis was very long and difficult, and in cachectic cases was useless. In such he preferred the application of ligatures to all the larger arteries, with the view of causing atrophy, followed by curetting. This was a good and harmless palliative operation.

Dr. Jessett, of London, laid it down as a general principle that there were very few operative cases which could not be done per vaginam. His experience extended to one hundred and forty cases. It should be remembered that coincident thickening of the broad ligament might be of an inflammatory nature and not malignant. Cases, from an operative point of view, should be classified according to their situation: (1) The os; (2) the inner part of the cervix; (3) the fundus. Those of the second group were the most unfavorable for operation, on account of early extension. Those of the third class were especially encouraging, involvement of glands being usually late.

Dr. La Torre, of Rome, believed in the abdominal route, but limited operation to cases in which the lesion was early. In a case of vaginal excision he had seen recurrence in the scar.

Dr. Janvrin, of New York, said that for the last fifteen years he had operated mainly by the vaginal route. He believed that when, so far as could be ascertained, the lesion was confined to the cervix, or to the fundus, or to the endometrium, and there was no involvement of the ligaments or the glands, the vaginal operation was the best. When the disease had progressed beyond these limits, the abdominal operation was to be preferred, because it was more thorough. At the same time there was great lack of reliable statistics as to results in operation by this route in the class of cases indicated.

Dr. Reynier summed up. He agreed with Dr. Doyen and Dr. Jacobs that extensive cases should be left alone; but the difficulty of clinical diagnosis should be remembered, and surprises on opening the abdomen were frequent. Therefore the difficulty in regard to hemorrhage from friable cancerous tissue was of practical interest.

**The Clinical Significance of Retrodeviations of the Uterus.**—Dr. Heinricius, of Helsingfors, read a paper with the above title. After enumerating the various symptoms usually ascribed in text-books to retrodeviations of the uterus, the speaker proceeded to show that no one of these (bleeding, sacro-lumbar pains, dragging pains, dysmenorrhœa, sterility, compression symptoms, etc.) nor any combination was characteristic. He had often seen so-called compression symptoms (vesical and rectal) in the presence of a retrodeviation which mechanically could not possibly have caused them; and he believed they were usually nervous reflex manifestations, due to the malposition of an important organ. He would conclude that retrodeviations had no causative effect in the production of the symptoms usually ascribed to them, which were dependent probably on coincident conditions; and he believed that operation for the malposition *per se* was unnecessary.

Dr. Ziegenspeck, of Munich, agreed with the preceding speaker, and cited illustrative cases, *e.g.*, one patient in whom retroflexion had persisted, but the symptoms had disappeared under treatment of complications, endometritis and oöphoritis. He disagreed, however, with his remark concerning non-operation, believing that the retrodeviation should be operated, inasmuch as it was liable to cause a certain amount of torsion of vessels, and, consequent upon this, stagnation of the blood current, hypersecretion, increased liability to infection, and thus endometritis.

Dr. Goldspohn, of Chicago, urged operation as a rule. He compared the retrodeviated uterus to a reducible hernia. It should be operated because it tended to become complicated.

Dr. Engström, of Helsingfors, was strongly in favor of the essayist's view. In seven hundred cases of retroflexio uteri mobilis in the past four years, he had treated only two per cent. for the retroflexion *per se*.

**Operation for Stenosis of the Os.**—Dr. Ziegenspeck, of Munich, read a paper with the above title. He believed that gradual blunt dilatation was still the best treatment. With discission and Kehrer's stellate incision, recurrence of the stenosis frequently occurred. He based his own operation on the principle of the Y-shaped incision and V suture line. He chose, as site, the middle of the anterior and posterior lips of the cervix, because lacerations were most commonly lateral. He had done the operation only three times, keeping it as a last resort. In the first case, pregnancy had occurred soon afterward after long sterility. The other two cases he had lost sight of.

**Total Abdominal Castration in Affections of the Adnexa, whether Septic or Non-Septic.** — Dr. Jonnesco, of Bucharest, read a paper with this title. He would insist on the advantage of the abdominal route over the vaginal. It had been claimed that the vaginal operation was a complete one. This was not so. He had frequently observed that a healthy uterus had been removed, and diseased adnexa left. He thought that in half the cases the operation was incomplete, abdominal section being later necessary. The adnexa being septic and the uterus apparently healthy, should the uterus be left? No. It should be also removed, because (according to Wissner's statistics of over one thousand cases) the results in over one-half the cases were unfavorable, and the uterus had to be removed subsequently. This operation had scarcely any greater mortality than oöphorectomy alone. His own series showed, in the first series of thirteen, a mortality of four. Since then he had had twenty-nine cases without a death. He would also advise the same operation in non-septic ovarian lesions for cases in which the ovarian cyst was firmly adherent to the uterus. If left the uterus soon became infected.

Dr. La Torre, of Rome, urged conservatism. He had made impartial statistics, which showed that those in whom the total operation had been done were much worse off, as regards subjective symptoms, than those in whom the uterus had been left.

Dr. Reynier, of Paris, said that he also had early shown the incompleteness of the vaginal operation. Yet in suppurative cases it was to be preferred because it involved less risk of a fatal issue. If the uterus was infected, of course it should be removed. Otherwise he preferred leaving it, as in that case menstruation persisted to a slight extent, a thing usually appreciated by patients.

Dr. Straatz supported the views of Dr. Jonnesco.

Dr. Hartmann, of Paris, said that so far from the total operation being more dangerous than the removal of the adnexa alone, it was, on the contrary, more benign. His personal statistics gave forty total operations with one death. Those of another surgeon had given seventy-two cases with two deaths.

**Intra-Uterine Implantation of the Ovary.**—Dr. A. Palmer Dudley, of New York, read this paper. He remarked that although ovarian transplantation had been successfully done by Glass, of Utica, and Robert Morris, of New York, implantation of the ovary into the fundus of the uterus had never, so far as he knew, been performed. The case report concerned a woman, aged twenty-one years, who suffered from an acute double pyosalpinx, with pyuria and

albuminuria. She was a prostitute, and had had a miscarriage at the second month shortly before she came to him viz., May 24, 1899. The uterus was curetted and washed out with bichloride 1:1,000. Then laparotomy was done, and the tubes were removed. The fundus was laid open by a vertical incision; the ovary was cut from its ligament, washed in saline solution, doubled up, and fastened by a silk suture into a spot in the fundus prepared for it by cutting out a small wedge. The uterus was then closed, and a small gauze drain used. The patient was carefully watched, and the ovary was certainly not discharged through the vagina. Menstruation had occurred one week before the operation; it came on as usual three weeks after the operation, but was not painful. The pyosalpinx was found to be gonorrhœal. She was discharged in good condition thirty days after the operation. Being seen again on July 28th, her condition was found to be very good; she had no pain on menstruation; no leucorrhœa; no pain on intercourse. On examination the uterus was found normal in position and size. Menstruation had recurred on July 9th, not so profuse as formerly, but without pain. It would be interesting to see if conception would occur; but in a prostitute such was unlikely. He concluded that plastic work of this nature was justifiable and not dangerous, inasmuch as it enabled the patient to escape premature menopause with its reflex phenomena.

Dr. Dudley also presented a paper entitled "A Further Report upon Conservative Surgery on the Uterine Appendages," reprinted from the *American Gynæcological and Obstetrical Journal* for October, 1898.

**New Palliative Treatment of Cancer of the Uterus.**—Dr. Jouin, of Paris, read a paper with the above title.

(*To be Continued.*)

## THE BRITISH MEDICAL ASSOCIATION.

*Sixty-Seventh Annual Meeting, Held at Portsmouth, August 1, 2, 3, and 4, 1899.*

(Special Report for the Medical Record.)

### GENERAL SESSIONS.

*Second Day—Wednesday, August 2d.*

(Continued from page 286.)

**The President-Elect.**—The council recommended that the next meeting of the association be held at Ipswich in 1900, and that the president-elect should be Dr. W. A. Elliston of that place. The recommendation was unanimously adopted, and Dr. Elliston was declared elected.

Dr. Elliston thanked the members for bestowing on him the honor. To be the head of that association, which was, he believed, the largest scientific society in the world, with seventeen thousand members and branches in every part of the British Empire, was sufficient to satisfy the ambition of any member. He was aware of the responsibility of the position in which he was placed, and he pledged himself to be true to the interests of the association and the profession at large during his year of office. On behalf of the ancient borough of Ipswich, he assured the members that they would find there in 1900 a reception worthy even of the British Medical Association.

**Address in Medicine.**—Sir Richard Douglas Powell, Bart., M.D., F.R.C.P., then delivered the annual address in medicine. Thinking over the best way to fulfil the task which he was honored by the request of the council to perform, it had occurred to him that a few remarks on the developments of medicine from one in the current of practical work might be more interesting and appropriate than any more exhaustive discussion upon some one topic. Such remarks must necessarily be incomplete and fragmentary, reminding the hearers of what they already know in detail, suggestive of the trend of medical opinion to-day, and perhaps reviewing some of the changes in doctrine and practice within recent times. As in the past, so in the future, medicine, whether as a philosophy, as a science, or a beneficent calling, promised ever to find employment for the most cultivated, the most practical, and the best-ordered intellects of the time. At no previous period in its history could its branches and offshoots give better promise of bearing fruit for the good of humanity to those who should cultivate them with industry and scientific zeal. We were certainly better equipped for exact diagnosis now than ever before, and possessed a larger and more precise knowledge of a greater number of diseases. It was probable that the introduction of photography into clinical medicine, and the more general use of bacteriological examination and surgical exploration, might, for a time at least, dim the prestige of auscultation and palpation in diagnosis. It should not be so. Happily we already saw a revival of the appreciation of the pulse in practical medicine; except in clinical wards and the physiological laboratory the sphygmograph may be said to be already past. The late Sir William Jenner classified the thermometer with the stethoscope in clinical medicine, and but a few years before he did so the instrument was looked at askance by the greatest of physicians. It was as important in bedside medicine to-day as the barometer and compass combined were in navigation. A better knowledge of the habits and vital history of the micro-organisms, upon whose doings pyrexial phenomena so largely depended, informed us that their initial attack and greatest activity were at the lower ranges of temperature, and that the higher ranges, the results of such activity, were more or less inhibitive to their well-being; so that, given a febrile disease, we must accept without necessarily interfering with a temperature normal to it. The clinical study of anomalous fevers had gradually convinced us that in their development and full activity specific poisons might overlap one another in the same illness; a rational treatment of specific diseases must be guided by the recognition of these superfactors. Tubercle in tissues at rest and protected from impure atmospheric contamination tended to obsolescence; our antiseptic treatment and our pure-air methods were mainly operative against such secondary infection. Time did not permit the speaker to do more than allude to the wonderful accession to preciseness in diagnosis as well as in successful treatment that had become possible of late years from the developments of surgery under Listerian methods. It must be confessed that bacteriology in its application to diagnosis and treatment in practical medicine was yet in its infancy; but it was an infancy full of promise, the complete fulfilment of which none of those present would live to see. The bacterial origin of tubercle, anthrax, diphtheria, erysipelas, septicæmia, typhoid, malaria, influenza, had been revealed to us almost within the memory of the youngest here, and had already been, in many instances, fruitful in suggesting measures of prevention and treatment. It was a matter for congratulation to see the departments of research and clinical observation approaching to closer communion in our great hospitals, a co-operation which could but be to the great advantage of the physicians, and, he ventured to think, scarcely less so to the research expert. He was in no way com-

petent to discuss the question of serum therapeutics from the bacteriological side. It was already an immense achievement if we had acquired the knowledge that every infection required a separately prepared serum for its treatment. While the possibility of neutralizing by appropriate treatment the specific poison in certain diseases would relieve practitioners of some anxiety, it could not fail, on the other hand, to add much to the tension of their labors by requiring an earlier diagnosis, and by the great care needed to avoid accidents in the use of delicate organic fluids prone to contamination and decomposition. It seemed possible that we might look in the near future for considerable development of preventive serum treatment in the prophylaxis of endemic diseases. Thirty years ago Sir William Jenner, in an address to the Epidemiological Society, declared the transmission of tuberculosis from parent to child to be one of the best-established facts in medicine. The susceptibility to become tuberculous ran in families—and this, he confessed, remained with him (Sir Douglas Powell) an unshaken belief. We could not, of course, prevent consumptive people from marrying; there were exceptional conditions under which they might rightly do so, but the advice of the family physician should be steadfast in discouraging such alliances, which were unfortunately often prolific. Tuberculosis was more prevalent among married than single people. Pulmonary consumption was comparatively rare before puberty, infantile mortality being almost exclusively from bowel consumption through milk infection. Tuberculosis was nearly twice as frequent among male as among female infants. The records of the officials and servants of one of our largest consumption hospitals taken out for fifty years, including a period precedent to the use of any special preventive measures beyond those of ordinary sanitation, showed a death rate not in excess of that of the ordinary population. While, therefore, on the one hand advising every ordinary measure of cleanliness, avoidance of dust, and proper disposal and disinfection of sputum, we might, and indeed must, avoid all exaggerated statements calculated to alarm the public as to the contagion of phthisis.

It was remarkable that two at least of the most deadly of disease microbes, tetanus and anthrax, should be normal inhabitants of the soil, and yet how comparatively scarce these diseases were, and, as regards one at least how communicable! With regard to tuberculosis he would make this final remark: that while we might hope, on the one hand, by further careful sanitation, by destroying and diminishing the careless distribution of bacillary dust, and by withdrawing from human consumption tuberculous foods, still to effect a considerable inroad upon the remaining fourteen per ten thousand mortality from consumption, we could not afford, on the other hand, to withdraw or relax precautions dictated by observations sound in themselves, although in some regards capable of amended explanation, or we might have to make some deductions from the two-thirds diminution in mortality already achieved. In his belief there was a mephitic laboratory beyond special control.

---

*Third Day—Thursday, August 3d.*

**The Address in Surgery.**—Prof. Alexander Ogston, of Aberdeen, delivered the annual address in surgery. After referring to the new era in surgery due to the influence of Lister and his teachings, the orator devoted the main portion of his address to a review of the condition of the medical departments of the army and navy. He pointed out that it was reasonable to expect that they should efficiently perform their functions in time of peace, and be fully prepared for the eventualities of war. With regard to the army medical service, oft-repeated experience had taught us to conduct expeditions in the jungles and swamps of West Africa, the Nile deserts, or in the Himalayas in a way no other power could rival or excel. But could we infer from this that we were in a condition to deal with a war against a great power, in which large numbers of wounded—thousands instead of tens—would fall to be treated? Even at present in time of peace the work of the medical department was carried out partly by the aid of civil practitioners, whose other occupations rendered them unfit for being effective and satisfactory army medical officers. But the maintenance of the army in health in peace was not what the country expected. The chief end of all departments of the army and navy involved preparation for war, and unless that end was fulfilled the department was only a pretence of what it ought to be. The ordinary routine duties in time of peace formed so great a contrast to what was to be expected in a European campaign that comparison was hardly possible. These routine duties afforded the army or navy surgeon no chance of acquiring the knowledge and skill that would be then required of him. He pointed out that practical familiarity with the details of antiseptic surgery, the methods of modern cranial, thoracic, and abdominal surgery involved years of constant practice and study. The axioms of Senn, of Chicago, were quoted: (1) That in theory and practice military surgery was equivalent in every respect to emergency practice in civil life. (2) That the wounded soldier was entitled to the same degree of immunity from infection as a person in civil life suffering from the same injury. (3) That all formal operations in war must be performed where the wounded could receive the full benefit of aseptic and antiseptic precautions. (4) That operative interference was indicated in all penetrating wounds of the skull. (5) That all gunshot wounds of the chest should be healed under strictest antiseptic precautions. (6) That laparotomy in penetrating gunshot wounds of the abdomen was indicated in all cases in which life was threatened by hemorrhage or visceral wounds, and the general condition of the patient was such as to sustain the expectation that he would survive the immediate effects of the operation.

Statistics proved that of all wounds in battle 7.4 per cent. were in the brain, 7.5 per cent. in the chest, 4.7 per cent. in the abdomen, or 20 per cent. in all. In the next campaign there would therefore be a great field of usefulness for properly qualified surgeons. The great danger of sepsis in gunshot wounds was referred to, and Dr. Ogston believed that in the gunshot wounds of soft parts and the extremities a much larger proportion of lives and limbs might be saved than hitherto. He showed that in peace our surgeons had naturally no training to fit them for war. Except a few connected with Netley and Haslar, most officers had hardly once in their lives had an opportunity of carrying out an important operation on the head, thorax, or abdomen. How could they then undertake laparotomy for a gunshot wound of the abdominal contents? Under the existing system no junior army medical officer had an opportunity of practising modern surgery, so that few if any were capable of that class of surgical work which the country would expect of them in time of war. Also Netley and Haslar hospitals, limited to soldiers and sailors, did not offer the necessary varied material for surgeons and physicians to cultivate their art. And besides these there was an almost total absence of hospitals and lazarettos of a kind fitted to afford any facilities for the study required of medical officers.

The contrast between the medical and other scientific corps, such as the artillery, engineers, and telegraph

corps, was pointed out, those latter being in peace elaborately trained to their duties in war-time. "Even the care that has been bestowed on the development of the ambulance will result only in wounded men being now brought, on the best surgical principles, to surgeons rendered as unfit to treat them as it is possible for a bad system to make them." In the medical services, after obtaining their commissions, officers were denied any further opportunity of studying the scientific and recondite problems in which constant application was necessary. Not only surgical, but medical and sanitary work was required of medical officers in time of war. The army medical corps ought to be made a complete and perfect entity, fully equipped with everything needful, and regularly trained like any other department. An example was given of how the army medical service worked, in an expedition of eleven thousand men, sent under Sir Gerald Graham to the Eastern Soudan, and landed on the Red Sea littoral in 1885. In the bearer companies the men were from Aldershot, the carts and harness from Woolwich, the mules and muleteers from Spain, dhoolies and dhoolie bearers from India, camels and camel drivers from Aden. The wagons arrived in one ship, the harness in another, the mules in a third, and all at different times. When the ambulance wagons were landed along with several carts, the pieces were mixed up and the men had to fit them together as best they could. When the mules and harness turned up, it was found that while the wagons were made for one kind of draught, the harness was made for another, and so on. And the officers, non-commissioned officers, and men knew nothing of each other. For the medical part of the expedition, the stores came without storekeepers, and without proper outward indications of what the packages contained. Chaos reigned, and had there been any engagement on the day the forces landed, not a bandage would have been forthcoming for the wounded. Each field hospital should be completely furnished and frequently practised in its duties. Every corps should be ready to act, as in other departments, the moment it took to the field, and not have to learn its duties when the day of trial came on a campaign.

In the navy he considered work had to be carried out under arrangements that seemed deliberately calculated to render the practice of antiseptic surgery impossible—rooms without antiseptic materials, irrigators, or sterilizers, and with a limited armamentarium of instruments mostly provided at the expense of the medical officers, and no proper diagnostic instruments or apparatus. In the event of any naval engagement of magnitude the wounded on board our ships of war would have to be attended to in a small dark room, unprovided with any save the rudest appliances and a few cots, where at most half a dozen men could be handled, and which was moreover in many vessels as much exposed as any other part of the ship to the fire of the enemy. Were such a fighting-bay rendered untenable, the wounded, however great their need, could be attended to only by being lowered, slung in a vertical position, down the narrow hatchways where the shot was brought up from the magazines to the guns, and even these would not be available during the heat of action. Everything on board ship that could destroy life was of the highest perfection; everything that could save it of the rudest description and behind the age. In the care of a gunshot wound through the abdomen, the only chance of recovery was laparotomy performed within twelve hours, but on board none of her majesty's fleet was there any possibility of performing such an operation; there were neither accommodations, nor instruments, nor accessories. Or were twenty per cent. of the men of a battleship disabled in action, the wounded among them could not receive the attention due to them. He suggested the construction under the water line, shielded by the turtle-back armor-deck, of a sufficiently large well-lit space, fitted up with all that was required for wounds, compound fractures, and operations on the main cavities of the body. On the smaller vessels matters were worse still—no surgeon and no surgical appliances. On torpedo-boat destroyers there were no materials for making splints. If not a surgeon, at least several men fully instructed in first aid should be carried on these smaller vessels.

As to the lines of remedy, in continental countries in which universal military service existed the most eminent civil surgeons were at disposal in time of war, held rank in the army in peace, and received promotion like those actually serving. An endeavor might be made to attach a number of our most eminent surgeons to the Royal Army Medical Corps by giving them military rank and titles, with special privileges and emoluments. The attempt, however, to get civil practitioners to volunteer when war broke out would fail, since the graduates thus obtained did not belong to the experienced surgeon class, but were simply superior dressers. He pointed out that in Germany every medical man who had served in the army possessed a fixed military rank, and was liable to be called upon again if needed. Those who had not served in the army received an annual inquiry from the war office as to their willingness to serve in case of war. Each medical man was allotted in time of peace the military post he would occupy when war broke out. The university professors held high military rank, and were required to give annual courses of instruction to army and navy medical officers. Such well-known surgeons as Bergmann, Bruns, Trendelenburg, and Mikulicz had to teach these classes during the Easter holidays. In time of peace the most promising surgeons and assistant surgeons of the army were sent to do duty for a year at a time in large public hospitals, also to attend annually special courses in anatomy, surgery, and operative surgery. The senior medical officers had to serve in rotation in large military hospitals, in which cases of all kinds, not merely military, were treated. They might be sent to attend courses of bacteriology, or be furnished with funds for travelling to other countries and studying their medical and sanitary arrangements. The state provided all instruments and appliances, and every hospital had a complete armamentarium provided for it. Russia possessed six large and three hundred small hospitals. The St. Petersbury military hospital received medical, surgical, gynæcological, ophthalmic, and other diseases, and consisted of five separate clinics or infirmaries. About forty-five thousand patients were treated per annum. The staff consisted of thirty-four professors, seventy privatim docentes, and forty-seven assistants. Everything to assist advanced work was present, such as *x*-ray rooms, photographic rooms, electrical rooms, immersion lenses, centrifuges, etc. Russia had three thousand surgeons in her army, and any showing ability and powers of work might apply for orders and be ordered to return to study in the hospitals for a period of two years. In France post-graduate courses for medical officers were conducted by professors at the different universities.

The speaker suggested the formation of a section of the British Medical Association for naval and military surgery only. Information as to the state of the services should be laid before the War Office and Admiralty. Medical provision should be made for three complete army corps; and the whole service should be organized as a body of independent units capable of being combined or acting alone as required. Above all, provision should be made for the proper instruction of officers in war duties. Study leave was of no use

so long as the service was undermanned. One year at least in every five should be devoted to this. Officers on study leave should be sent to act as assistants, residents, house surgeons, and physicians in our hospitals and medical schools. The hospitals and lazarettos at home and abroad should be multiplied, improved, and nourished into new life and activity. They were the heart of the services, and no more deadly injury had ever been done than by starving and neglecting them. As to the navy: for the succor of the wounded in time of war, fast, unarmored steamers, flying the Red Cross flag, fitted up with wards, sterilizing and apparatus rooms, operation theatres, dressing and anæsthetic rooms, should be provided and officered by a staff of surgeons and attendants. In fact, so far as possible a good civil hospital should be imitated. The military authorities were under the impression that any deficiencies could at any time be compensated by the power of money in engaging civil aid. This was absolutely erroneous. The civil aid at present employed at many stations was of inferior quality, and could not be made use of in war to any extent. The medical men who filled these substitutive posts, as well as those who would volunteer to aid in active service, were not the skilled and trained class who could be entrusted with the difficult surgery of gunshot wounds. The fatal error of imagining that the army medical corps could be supplemented by civil aid had already done infinite harm, and had been made a constant pretext for hindering the development of the services and producing the defects mentioned above; and were such a proposal made regarding any other scientific department, *e.g.*, the Royal Engineers, the absurdity would at once be perceived.

The Stewart prize for research in the origin and prevention of epidemic diseases was awarded to Surgeon Frederick James Abercrombie Dalton, R.N., for his original investigations in beri-beri.

---

*Fourth Day—Friday, August 4th.*

The last general meeting of the association calls for no special report, the principal business transacted consisting of votes of thanks to all and sundry who had contributed toward making the conference the great success it undoubtedly was.

**Resolutions of Sections.**—The President reported the following resolutions from the Sections:

Resolution passed in the Section of Psychology:

*Resolved*, That the Section of Psychology respectfully suggests that the council of the association be asked to consider the advisability of procuring early legislation for the well-to-do inebriates, and to refer the question to the various branches of the association for their opinions.

Resolutions passed in the Section of Medicine:

*Resolved*, That the council be requested to communicate to the War Office that it is the opinion of this section that the physical examination of candidates for the army should precede the educational.

*Resolved*, That the council be requested to communicate to the war office that it is the opinion of this section that soldiers ought not to serve in the tropics before the age of twenty-two.

*Resolved*, That the physical standard for admission to the public services requires reconsideration, and that the council be also requested to communicate this resolution to the War Office, the Admiralty, and the other governmental bodies interested.

Resolution passed in the Section of Ophthalmology:

*Resolved*, That the Section of Ophthalmology of the British Medical Association begs to express its profound belief that it would prove of great public benefit if the board of trade could see their way to include in their regulations the twelfth recommendation of the Royal Society's committee: "That in case of judicial inquiries as to collisions or accidents, witnesses giving evidence as to the nature or position of colored signals or lights should themselves be tested for color and form vision," and suggests its application in every case of judicial inquiry upon accidents at sea.

Resolution passed in the Section of Tropical Diseases:

*Resolved*, That the council of the British Medical Association be asked to convey the thanks of the association to the Right Hon. Joseph Chamberlain, M.P., Her Majesty's secretary of state for the colonies, for the interest he has shown in forwarding the study and teaching of tropical diseases in Great Britain, and especially for the active part he took in establishing the School of Tropical Medicine, London.

---

SECTION OF TROPICAL DISEASES.

*First Day—Wednesday, August 2d.*

**The President's Address.**—The president, Dr. George Thin, delivered an address on "The Etiology of Malarial Fever." It was but twelve months ago, he said, at the meeting of this section at Edinburgh, that Dr. Manson first announced Major Ross' discovery that birds could be infected by the direct bite of mosquitos whose blood contained the "proteosoma," and further that not all mosquitos, but only certain definite species, were endowed with the power of infection. From these observations the scientific investigations of the etiology of malarial fever dated. While Ross was working in Calcutta the Italian observers Grassi, Bignami, and Bastianelli were not idle. They practically, by carefully made experiments, confirmed all Ross's observations and conclusions. In Italy some districts were markedly malarial, while others were entirely free from it. By bringing mosquitoes from these several districts, it was shown that it was only when certain kinds of mosquitos from infected localities bit a human being, that malarial feverish symptoms developed. The Anopheles claviger was found to be the variety of mosquito which most persistently figured as the medium of transmission and infection. The development of the parasite of malaria in the body of anopheles seemed to be identical with the development of the proteosoma in the gray mosquito of Ross. If the mosquitos were placed in a temperature of 14° or 15° C. after they bit, no development of the parasite took place in their bodies. At 20° to 22° C. the parasites developed slowly, but at 30° C. more quickly. Seeing that the anopheles was the carrier of malaria, its habits and geographical distribution became a matter of the highest importance. The Anopheles claviger was widely diffused in Europe. It occurred in Scandinavia, Austria, Germany, Russia, and in Italy and the adjacent islands. The anopheles at one time, if not now, existed in England. In the United States of America several varieties of anopheles were also met with. Dr. Thin then proceeded to deal at considerable length with the opportunities afforded in this country for the study of tropical diseases, and claimed for Netley Hospital that it possessed the greatest facilities in that direction.

**The Rôle of Insects, Arachnids, and Myriapods in the Spread of Diseases due to Parasites.**—Dr. George H. F. Nuttall, of Cambridge, read a paper of which the following is an abstract: First: The rôle of insects in the spread of bacterial diseases. (1) Passive rôle—The domestic fly and allied species were chiefly to blame in this respect. Incapable of "biting," they might from the nature of the food they seek carry pathogenic bacteria in their bodies or within their alimentary canal and deposit them on lesions of skin or mucous membrane, or on food. It was possi-

ble, nay, probable, and in many cases scientifically proved, that anthrax, plague, cholera, typhoid fever, frambœsia, and Egyptian and "Florida" ophthalmia were so diffused. (2) Active rôle—Blood-sucking flies might play a part in propagating bacterial disease. Clinical writers reported that cases of anthrax, septicæmia, pyæmia, and erysipelas arose in certain instances from bites of flies; but experimental evidence was all against this statement. Experiments made by the speaker on animals with plague, anthrax, mouse-septicæmia, and chicken cholera all gave negative results.

Second: The rôle of insects, etc., in the spread of diseases due to animal parasites, insects, etc. While serving as intermediary hosts they might play—(1) a passive rôle, when they were devoured by a host of the parasites they contained; (2) an active rôle, when, as in the case of the tick in Texas fever, and various mosquitos in malarious affections of man and animals, they inoculated a host by means of their proboscis. (3) In filarial diseases an intermediary position was played by the mosquito, as it infected itself by sucking the blood of the definitive host. Insects, etc., without serving as intermediary hosts may play—(1) a passive rôle, when they transport eggs of animal parasites and deposit them in food, *e.g.*, eggs of tænia solium, trichocephalus, ascaris lumbricoides; (2) an active rôle, by carrying the disease from one animal to another and inoculating the parasite, *e.g.*, tsetse fly.

**A Case of Bilharzia Hæmatobia.**—Mr. C. P. Childe, F.R.C.S., stated that he had a woman under his observation who was suffering from all the symptoms of bilharzia infection. It was rare to meet with the disease among women, no doubt owing to the fact that they were seldom exposed to it as men were; but this patient, a white girl, aged sixteen years, had up to two years ago resided in Natal, where she frequently bathed in a pool of fresh water. Mr. Childe was of opinion that the parasite gained entrance to her body either by the skin or urethra, and asked whether any known drug or treatment could be suggested as a remedy.

Dr. Manson discredited the suggestion that the bilharzia gained entrance by the skin or by the urethra, and Colonel MacLeod said that, although drugs were useless to cure the disease, many persons suffering from bilharzia had reached old age.

**Filarial Periodicity.**—Dr. Patrick Manson read a paper on this subject. The singular phenomenon of the embryo filarial parasites appearing in a countless swarm in the cutaneous circulation during the night and disappearing from it during the day, he said, suggested the questions: (1) What was the object of it? (2) Was it constant? (3) What became of the young filariæ during the day? The answer to the first question was in all probability that the nocturnal appearance of the filariæ at the surface of the body was an adaptation of the habits of the parasite to those of the mosquito, its intermediate host. The answer to the second question was distinctly in the affirmative—filarial periodicity is constant. The third question, "What became of the filariæ during the day?" Dr. Manson was enabled to answer by a recent experience. A man suffering from filaria nocturna in his blood committed suicide by poisoning at 8:30 A.M. The hour is important, as about the time he died (he died almost instantaneously) the filariæ had retired from the peripheral circulation for the day. At the post-mortem examination seventeen filariæ Bancrofti were found in a varicosed lymphatic mass occupying a large part of the pelvis and abdomen. A hurried microscopic examination made at the time gave the following results: In the margin of the lung, a pulmonary artery and a pulmonary vein, embryo filariæ were met with in enormous numbers. A large number were found in clots of blood in the left ventricle of the heart and in the aorta. A few filariæ were found in the coronary artery and vein, in the right ventricle of the heart, and in a middle cerebral vein. No filariæ were seen in the bone marrow, in the spleen, and in the liver. Subsequent examinations of the blood films after fixing and staining had almost similar results. The number of filariæ in the blood expressed from the lung was prodigious, as many as thirty or forty being visible in some fields of a $\frac{1}{6}$-inch objective. Dr. Manson concluded from these observations that filariæ nocturna during its temporary absence from the cutaneous circulation was present in the large blood-vessels, particularly the arteries, and a few in the capillaries of the muscles, brain, kidneys, and heart muscle, but that the vast majority were lodged in the blood-vessels of the lungs. By what mechanism the filariæ maintained their position in the blood stream of vessels such as the aorta and carotids it was impossible to say.

---

*Second Day—Thursday, August 3d.*

**Psilosis or Sprue; Its Relations (Etiological and Pathological) to Other Forms of Tropical Diarrhœa, and Its Treatment.**—Dr. George Thin opened the set discussion on this subject by reading a paper entitled, "Notes on Psilosis or Sprue." The marked signs and symptoms of sprue Dr. Thin stated to be irregular and abnormal motions; there being, first, diarrhœa, varying much in severity, frequency, and persistence, disordered digestion, and progressive emaciation. Dr. Thin divided cases of sprue into four groups: (1) In sprue patients from the far East (Eastern Archipelago), the mouth, tongue, and throat symptoms were early prominent, with supervening diarrhœa. (2) Patients who contracted sprue in India exhibited copious, watery stools from the first; the mouth and tongue symptoms not developing until a later stage of the disease. In sprue patients from the far East, mouth and throat symptoms were very great, long before the disease had led to much debility or emaciation. The reverse was the case in sprue patients from India suffering from diarrhœa alba, a white flux; for with them "mouth" symptoms were usually synchronous with advanced malnutrition and emaciation. (3) A form of chronic diarrhœa occurred in elderly persons or in persons of long residence in the East. It was characterized by looseness of the bowels, gradual thinning of the epithelial covering, and considerable rawness of the tongue. (4) In persons who have been in the East intestinal symptoms might develop long after they have returned to Britain. In reference to the pathology of the disease little was known. There was a general atrophy of tissues and organs, and there was a special connective-tissue development—a true sclerosis—of the submucosa of the intestine, more especially of the ileum. The cause of this irritation was unknown, but that the irritation may be sufficient to produce an enteritis was shown at the post-mortem of a patient who died from a very acute attack before emaciation had occurred. The ulcerations described by Bertrand and Fontan as occurring in the intestine Dr. Thin was inclined to consider of secondary consequence. As regards etiology, sprue appeared to be a specific disease associated with residence in certain parts of the world and absent in others. The poison, whatever it is, altered the secretion of the small intestine and allowed the food bolus to retain its acidity; it destroyed the coloring matter of the bile, and seemed to develop freely when farinaceous and animal foods were given. The poison appeared to be starved out by limiting the patient's

diet, and when the food consisted exclusively of milk, and in some cases by an exclusive diet of meat juice.

Dr. Henderson, of Shanghai, said that in 1868, when he began practice in Shanghai, no distinction was made between cases of chronic diarrhœa and the cases now known as "sprue." In Shanghai two types were met: first, patients of long residence in the East, who, during it may be twenty or more years, had enjoyed good health. In them a morning diarrhœa gradually developed, and a sore mouth, intermittent in character, supervened. In the second class were patients who after only five or six years' residence might become the subjects of sprue. In these patients there was a previous history of bowel complaint occurring for the most part during the hot weather. During one of the occasional attacks of intestinal flux the mouth became sore and the diarrhœa was established. The diarrhœa and sore mouth went hand-in-hand in sprue. Dr. Henderson stated that he had seen the mouth lesions remain after the stools had become solid as the result of treatment, but he had never seen sore mouth precede diarrhœa. Death in sprue was brought about by a process of gradual starvation. Post-mortem evidence showed that there was diminution in size and weight of nearly all the organs and tissues of the body. The liver was especially small, but perfectly healthy when cut into; the atrophy of the mucous membrane was apparent throughout the whole alimentary canal. It was impossible, of course, to say whether this was due to starvation or to the effects of the original cause of the disease. Independently of treatment by diet, milk diet more especially, Dr. Henderson had found a preparation made by boiling together simaruba bark three ounces, cinnamon bark one ounce, in three quarts of water until reduced in bulk to one quart, when one and one-half ounces of brandy were added, to be very efficacious. The dose of the mixture thus prepared was a wineglassful three or four times daily.

Dr. Watson, of Portsmouth, reported the case of an English lady who contracted an intestinal flux in India. Shortly after her arrival in India she had a sharp attack of dysentery. During the commencement of the next summer the patient developed distinct symptoms of sprue, *i.e.*, within fifteen months of her arrival in northern India. The characteristic stools developed while living at a low hill station in India. On a milk diet the symptoms disappeared, only to recur, however, when a more varied diet was resorted to. On leaving India on account of her condition she enjoyed perfect health on the voyage home, but two months after reaching England the disease recurred. By milk diet and rest in bed all symptoms again disappeared, but during a stay in South Europe (San Remo), whither she had gone to pick up, a relapse occurred. Subsequently the tongue became inflamed, raw, and tender, and it would seem that true sprue had set in.

Mr. James Cantlie, of London, stated that in the treatment of sprue and, in fact, in almost all cases of intestinal flux, he had ceased to administer milk. He trusted to a meat diet, commencing, if need be, with raw meat juice or scraped beef, exhibited frequently, even every half-hour if the patient was very weak. Later, when the severe symptoms disappeared, finely minced beef, lightly and rapidly cooked, in quantities of five ounces at a time, were to be given thrice daily. A plain calf's-foot jelly to allay the feeling of hunger was allowed the patient between meals and during the night. Rest in bed, a wet pack applied to the abdomen twice daily for two hours at a time, and fixed by a large binder (bath towel) tightly bound round the abdomen, were useful and essential parts of the meat-diet treatment. By a milk diet a stool of deceptive hardness was induced. It was pale, non-fecal in character, and was composed of cheesy masses of condensed curd of milk. A meat diet brought down a markedly bilious stool, helped to exercise the hepatic functions, and thereby increased the size of the atrophied liver. Milk relieved the symptoms, but by meat alone could a cure be effected.

Captain Lamb, of the India Medical Service, said the tendency of milk to form curd in the intestines might be thwarted by adding citrate of soda (1:400) to the milk.

Major Giles, of the India Medical Service, doubted if he had ever seen a case of sprue in northern India which answered in all points to the disease described by medical men practising in China. He had seen many cases resembling the one described by Dr. Watson, but the general opinion in India was that they were merely hill-diarrhœa. The speaker believed that "hill diarrhœa" was a condition in which the hepatic function was suspended, and that it was brought about by the treacherous chills of the hill climates in India, although it was in no way confined to the hill stations.

Dr. Manson said that sprue was met with anywhere in the tropical and subtropical zones, and he had seen cases from China, Japan, the West Indies, India, etc. It would appear that in the case of sprue and associated ailments we were dealing, not with a single disease, but a group of diseases, caused, it might be, by a variety of factors, as in the case of dysentery. Sprue was perhaps an example of disease attacking an organ or organs which had been exhausted functionally by the demands of climate. Dr. Manson stated that he had seen a case of sprue in which mouth and throat derangements were alone met with, diarrhœa not developing until some time subsequently. He did not consider that any one line of diet or any drug could be considered a specific in sprue; but that a diet consisting solely of milk, of milk with fruits such as bananas, of meat alone, or of a mixed character, should be employed as the condition of the patient would seem to justify. Rest, and above all warmth, were essential factors in the treatment of sprue.

Dr. Mullick, of Bombay, stated that he had never seen sprue among natives of India. From experience gained in England in two cases of sprue he had observed great benefit accrue by using koumiss as a diet instead of milk.

Inspector-General Turnbull, of the Royal Navy, in reply to a question by the chairman, Colonel MacLeod, said he had never seen sprue occur on board any of her majesty's ships; he had met, however, with a few cases of sprue in naval hospitals at home in men who had served on the China station. Dr. Turnbull described a case in which the meat diet recommended by Mr. Cantlie was attended by excellent results.

Dr. Sambon, of London, did not consider the differences mentioned in the seat of the lesions peculiar to sprue as of sufficient importance to justify dividing the disease into two classes. The geographical distribution of sprue seemed to point to its being a distinct disease. The specific germs probably became parasitic at an early period, but it was when low health or metabiosis supervened that the disease manifested itself.

Dr. Rho, of Italy, said that French observers in Cochin-China affirmed that minute ulcerations and erosions occurred in the lowest part of the ileum and the whole length of the colon. The same authorities also declared that traces of blood were always found in the stools of sprue patients at the beginning of the disease, and they regarded sprue as a residual of a chronic dysenteric state. He said that the condition of the intestine met with in sprue resembled the condition of the stomach found in Reichmann's disease, which was

characterized by dilatation of the stomach, sclerosis of the wall, and great secretion of very fluid mucus (gastro-succorrhœa).

Colonel MacLeod remarked that in Northern India the disease recorded by medical practitioners in China could scarcely be said to occur. Hill diarrhœa resembled in many points the signs and symptoms met with in sprue, but the "mouth" symptoms were never of the characteristic nature described by observers in China.

Capt. W. J. Buchanan, of the India Medical Service, contributed a paper to the discussion on sprue, in which he stated: (1) That primary or protopathic sprue was common among natives of India; (2) that secondary sprue following on dysentery and acute entero-colitis or enteritis was common; (3) that incomplete or arrested sprue was probably very common; (4) that the condition known as "famine diarrhœa" was essentially the same in its symptoms and ultimate results as sprue; (5) that in many cases of chronic relapsing dysentery a condition strongly resembling sprue was met with, and that characteristic frothy pultaceous diarrhœa alternated with the dysentery.

Dr. Thin, in reply, remarked that there was no evidence that the liver was diseased in sprue, or that the shrinking depended on anything more than the persistent diarrhœa and general wasting. The white stools passed with a milk diet did not consist of undigested milk. Milk in the earlier stages was the best diet; but in the later stages of the disease a meat diet was efficacious.

A discussion arose concerning the treatment of sprue by santonin as recommended by Dr. Bigg, of Hankow, but several speakers declared they had employed it without benefit.

**Suprahepatic Abscess.**—Mr. James Cantlie, of London, read a paper on the symptoms, pathology, and treatment of a disease which he defined as follows: "By a suprahepatic abscess was meant the formation of pus between the layers of the broad ligament of the liver, having as boundaries the peritoneum circumferentially, the liver below, and the diaphragm above. The affection might be unattended by hepatitis, dysentery, or any other abdominal ailment. It was characterized by a sudden onset, symptoms of fever, cough, and some respiratory distress and lung congestion, and, when allowed to pursue a spontaneous course, usually terminated by the pus finding its way through the diaphragm and lung to a bronchus from which the purulent matter was expectorated. Mr. Cantlie objected to the term "liver abscess" being employed as the name for a definite lesion. He believed hepatic abscesses could be scientifically grouped under three headings: supra-, intra-, and infrahepatic, differing in etiology and pathology. Suprahepatic abscess commenced as a lymphangitis of the vessels between the layers of the broad ligament of the liver, the result of chill; an inflammatory effusion speedily ending in pus caused an area of dulness on percussion between the liver and right lung in the neighborhood of the right nipple line. The dull area was shaped like an inverted saucer or cup on the upper margin of the liver, with its highest point usually internal to the right nipple line. The pus, when withdrawn by an aspirating needle before the abscess burst, was invariably sterile. Mr. Cantlie considered an abscess in this situation to be of non-dysenteric origin, and affirmed that the discussions which have so long been associated with the question of the dysenteric or non-dysenteric etiology of hepatic abscesses were thus explained. He thought it improbable that abscesses arising from ulcerative lesions in the intestine could present a sterile pus, and was of opinion that the supra-hepatic abscess was the true "non-dysenteric" and "sterile pus" abscess. As regards treatment, Mr. Cantlie recommended early aspiration as a prophylactic and as a means of diagnosis. When pus was found, tapping through the thorax by a trocar and cannula, and drainage by a large-sized india-rubber tube, as recommended by Manson, were attended by better results than when incisions were made to reach the seat of the abscess.

Dr. Manson remarked that the sterility or apparent sterility of liver-abscess pus might be explained by the micro-organisms having died out. The amœba coli was often missed when pus from the liver was examined, from the fact that the amœba did not occupy the centre, but lay on the wall of the abscess, and should be searched for in the discharge from the drainage tube some days after the operation.

Dr. Sambon refused to recognize that pus from the liver could be primarily sterile. A collection of pus must have been caused by some kind of irritant. When an amœba was not found it was probably because it had been destroyed; in fact such a phenomenon might be expected as the result of phagocytosis.

Captain Lamb stated that not only were abscesses containing sterile pus found in the situation described by Mr. Cantlie, but also in the liver substance itself.

Dr. Rho, of Italy, stated that supra-hepatic abscess was not a disease of tropical countries specially. Both supra-hepatic and supra-splenic abscesses were met with in temperate climates, and they depended upon some chronic disease of the intestine of an ulcerative nature.

Dr. E. Charles, of Falmouth, attached great importance to the presence of a leucocytosis as a means of diagnosis in suspected cases of liver abscess. He inclined also to the opening of hepatic abscess by way of the abdominal wall rather than by the thorax.

Dr. Henderson, of Shanghai, spoke strongly in favor of the metal drainage tube recommended by Dr. MacLeod, of Shanghai, as being in less danger of getting nipped between the ribs, and thus being occluded, than was the case with india-rubber tubing.

**Dysentery as a Terminal Symptom of Disease in the Tropics.**—Capt. W. J. Buchanan, of the India Medical Service, contributed a paper calling attention to a form of dysentery which supervened in the later stages of many diseases in India. He said: "As will be seen from the following twenty-eight cases, this 'terminal' dysentery (as I call it) frequently supervenes in the last stages of many chronic diseases; it is a certain symptom of impending death, and may commence even three or four days before that event takes place." Of the twenty-eight cases given in detail all the patients had been in hospital for some other severe illness. The dysentery in most cases was of a low gangrenous type, and in some of a more acute nature. Captain Buchanan believed the condition was essentially a degenerative process and more allied to noma or gangrenous ulceration of the buccal membrane than to any one of the many more pronounced types of dysentery.

Dr. Manson, in his remarks on the paper, said that these cases illustrated the fact that in healthy conditions, when resistance was normal, one of the germs of the many forms of dysentery, as probably of cholera and other disorders, might be present in the alimentary canal and not cause any pathological effect, but when the individual was depressed the parasites might become pathogenic.

Mr. Sambon said that the parasites in dysentery, as in black-water fever and sprue, etc., might be latent for months and years in the system, but under favorable conditions—low health, metabiosis—they might suddenly manifest themselves in typical attacks of their respective diseases.

Colonel MacLeod mentioned the special prevalence of terminal dysentery in leper asylums, but it

was also common in lunatic and other asylums in Europe. It was especially common in certain dwellings, and, like beri-beri, yellow fever, etc., might depend upon environment. It would seem that "terminal" dysentery was a preventable disease, which, like hospital gangrene, we might hope to get rid of.

**Hæmoglobinuric Fever and Paludism.**—Surgeon W. H. Stalkartt, of the Royal navy, read a paper on this subject, in which he stated that men on board ship on the West and East coasts of Africa were seldom if ever attacked by black-water fever; again, that on the Zambesi and Shire rivers there was a practical immunity of the troops. The disease occurred only after prolonged exposure in regions where the fever was endemic. Besides intertropical Africa black-water fever was met with in Sicily, Sardinia, tropical and sub-tropical America, New Guinea, and in the Indian Archipelago. In Australia and in many districts of India the disease was unknown. The speaker related a case of black-water fever in which quinine was given as a precautionary measure against malaria, and in which black-water fever did not recur. He stated that the circumstances which bore strongly against the hypothesis of black-water fever being malarial were the limited distribution of the malady and its non-occurrence in certain highly malarious regions. He regarded black-water fever as a distinct disease, possibly malarial in nature, and did not believe that it was ever due to quinine poisoning.

Dr. Manson grouped the arguments for and against black-water fever being malarial as follows: (1) Arguments for regarding black-water fever as being a malarial disease: (*a*) It occurred in highly malarial districts; (*b*) the malarial parasite was often found in the blood; (*c*) the disease occurred in persons who had had many attacks of malaria; (*d*) prolonged residence and consequent malarial saturation were usually antecedent to an attack of black-water fever. (2) Arguments against regarding black-water fever as malarial: (*a*) Its limited geographical range as compared with malaria; (*b*) the malarial parasites were not always found, and even when found they were not always of the same kind; (*c*) it was not certain that the fevers preceding attacks of black-water fever were really all of the true malarial character; (*d*) cases had occurred within a short period of a person's arrival in a region where the fever was endemic; (*e*) the epidemic seasons of malaria and black-water fever did not always correspond; (*f*) the disease was not amenable to quinine.

Colonel MacLeod stated that although he was acquainted with cases resembling black-water fever in India, the symptoms developed as a sequence to malarial fevers, but they were not to be confused with the true black-water fever met with in Africa.

Major Giles, I.M.S., said that the cases of malaria complicated with black-water fever met with in India were not attend by a pronounced mortality as in Africa, and it would appear that the resemblance did not extend beyond the alarming symptoms common to both, and that the diseases were really quite distinct.

Dr. Rho regarded Sambon's theory of black-water fever as the most satisfactory, having in its favor all the arguments which by analogy we could get from the hæmoglobinuria of cattle or Texas fever. Several Italian observers, Tomaselli, Murri, and others, had ascertained the fact that in some malarial subjects a very few centigrams of quinine could give rise to an access of fever with hæmoglobinuria.

Mr. Rees, of London, stated that the seasonal differences of black-water and malarial fevers were most marked at one station on the Niger, where, as the malarial curve decreased, the black-water fever curve gradually increased. He said that his experience was against the idea that hæmoglobinuric fever was due to quinine poisoning. Quinine was taken largely in Nigeria as a prophylactic, and those who adhered to quinine most carefully seemed to escape black-water fever. Mr. Rees stated that he had known cases of black-water fever contracted within two or three months of arrival in Africa, and he was not of opinion that it was either malarial or due to quinine.

Dr. Thin remarked that in addition to the case he had recently published, in which a man who died of black-water fever was found to have the parasite of malaria in the blood-vessels of his brain and pigment in the spleen and liver, he had examined portions of liver and spleen in another case and found pigmentary deposit in these organs sufficient to indicate an acute malarial attack.

Dr. Mould mentioned that a patient under his care in hospital for a sprained ankle developed black-water fever. He had had no quinine for three weeks and no malaria.

Dr. Porter had seen in Liverpool cases of black-water fever from the West Coast of Africa. He asked whether the fevers met with in Colon, Jamaica, Honduras, and Brazil were not of the same nature. He regarded black-water fever not as a distinct disease, but merely as a symptom.

**Thermic Fever (So-called Siriasis), with Special Reference to Its Alleged Microbic Causation.**—Colonel MacLeod, of Netley, discussed Dr. Sambon's view of this question, namely, that so-called thermic fever was not due to heat *per se*, but to a microbe called or recalled into existence and activity by excessive heat under certain circumstances, climatic, local, and personal. The name "siriasis," revived by Dr. Sambon and adopted by some, did not advance our knowledge or nomenclature. The word, derived from Sirius, the dog-star, would seem to imply that sunstroke is more common during the "dog-days" (July 3d to August 11th), but such is not the case, at any rate in India. No positive evidence had been advanced regarding the existence of a special microbe in cases of thermic fever. It had been shown indeed by Stiles that the injection of blood, taken from subjects of the disease, into a healthy person did not induce any pathological disturbance, therefore excluding the presence of either infective microbes or toxins in the circulating blood. Dr. Sambon's reasoning, that a microbe is present, was by a process both of analogy and exclusion liable to fallacy, and the constructive evidence he thus arrived at was very feeble. There is one analogy, however, he had neglected to draw, namely, the analogy of the effect of reduced temperature or cold. The chilling of the body was as dangerous as the heating, if not more so. Almost all the arguments advanced by Dr. Sambon could be employed here, *i.e.*, the phenomena caused by over-chilling were peculiar and definite, as were those of over-heating: the incidence of cold stroke had some resemblance to the incidence of epidemic disease, being in some instances single or sporadic, in others multiple, simultaneous, or quickly successive; hygienic and dietetic conditions affected heat conservation as well as heat depression; the duration of attacks, many or few, grouped or otherwise, was precisely limited by the duration of excessive cold in one case and excessive heat in the other. The parallel was almost perfect, and yet no one thought of invoking a microbe to explain the effects of cold. Dr. Sambon's argument by exclusion, the speaker continued, was also very weak. It took this form: excessive heat, solar and artificial, could be endured *per se* by the human organism with impunity, therefore something in addition was necessary to render it noxious. Now, Colonel MacLeod said, experiments prove that animals exposed to great heat died with symptoms resembling sunstroke in man. These Dr. Sambon set

aside as inapplicable in man, but without reason or fairness. Dr. Sambon further maintained that cases of heat stroke, as distinguished from heat fever—of exhaustion, syncope, and shock—were excluded on the ground that they were due to defect in the subject rather than to the potency of heat influence. This was not the case, as perfectly healthy people suffered from sunstroke. The speaker took the view of sunstroke put forward by Hertz and Wood. He also pointed out that just as hepatic exhaustion succeeded hepatic stimulation, so continued exposure to heat impaired the power of resistance to heat, and one of the principal sequelæ of heat stroke was an incapacity to endure or resist heat.

Dr. Sambon said that the idea that siriasis was explicable only by microbic action was gaining ground daily, and he had every confidence that not only would his opinion be confirmed, but that the microbe would be found. In fact, Wood of Philadelphia had described a microbe, and experimental proof was alone wanting to settle the point definitely.

Major Giles said that the fact that sunstroke had a geographical distribution supported Sambon's theory. He had seen soldiers in Natal working at a temperature which in other countries would in all probability have induced sunstroke. In Natal, however, sunstroke was unknown.

Dr. Watson said his experience was that men exhausted from want of food, and who took an excess of alcohol, were most liable to sunstroke.

Dr. Manson said that some organisms thrived at high and some at low temperatures; but it must not be assumed that because sunstroke occurred at high temperatures, a high temperature was the cause. The organism, if such there was, affected only certain parts of the world. This consideration was alone a very important one, and favored Dr. Sambon's idea.

Dr. Thin considered that direct sunlight as distinguished from simple heat had much to do with the causation of sunstroke. He thought that in many instances sunstroke was at least partly due to the direct effect of light through the eyes.

Dr. Rho said that he would divide sunstroke into two classes: the first, real sunstroke, occurred sporadically with no very high temperature; the second was epidemic in nature and accompanied by hyperpyrexia. The former was probably due to fatigue and toxins of the body; the latter, as contended by Dr. Sambon, was probably infectious and due to microbic infection.

Lieutenant-Colonel Boileau and Dr. Parker also joined in the discussion.

Lieutenant-Colonel MacCartie, of the India medical service, contributed a paper appertaining to the discussion on sunstroke, in which he stated that soldiers were more liable to heat apoplexy than any other class, because of the nature, texture, and quantity of their clothing, and because, owing to their uniform, their clothes were so buttoned up and strapped down that the air could not circulate about their bodies. He had seen men in mufti in India marching alongside soldiers in uniform, and although carrying heavier loads than the soldiers, they came in fresh and fit at the end of the march, whereas their brothers in uniform were utterly exhausted and some of them suffered from heat apoplexy.

**Antivenin.**—Surgeon O. W. Andrews, of the Royal navy, read a paper which dealt with wellnigh the whole subject of antivenin, and included a detailed account of a series of experiments performed by Major Semple, Major Lyons, and Staff-Surgeon Andrews. The composition of venom, Dr. Andrews pointed out, had been investigated by Dr. C. T. Martin, who said that venom consisted of coagulable proteid and non-coagulable proteid, and that the coagulable proteids might be regarded as albumoses rather than as globulins, the albumoses being those known as hetero-, proto-, and deutero-albumose. The venom of snakes was not a simple poison, but was composed of at least two distinct poisons: one of them, having the power of producing hemorrhagic extravasation and intravascular clotting, was destroyed by heating a solution of venom to 85° C., but there was another or others not destroyed by heating to the temperature of boiling water (100° C.). Heating to 102° C. for twenty minutes completely destroyed all toxicity of venom. Calmette maintained that the action of antivenine serum was in no way a chemical reaction but a physiological process, by which the white blood corpuscles were stimulated to carry on intracellular digestion, which he regarded as a variety of phagocytosis. M. Calmette considered that the venin is destroyed only within the leucocytes, and if the amount of serum injected before, with, or after the venom had been sufficient to impregnate the leucocytes so that they could carry on this process of digestion, the animals would resist lethal doses of venom, in the same way that animals vaccinated against specific diseases resisted them. The dose of serum required to protect a man against a lethal dose from the most venomous serpent was from 10 to 20 c.c., but additional security would be afforded by increasing the dose to 30 c.c. or even 40 c.c.; no ill effects attended the injection of the serum.

Mr. Rees said that he could confirm a statement made by Dr. Andrews, namely, that one of the two toxins of venin produced intravascular clotting. He had seen two fatal cases in Nigeria in which marked thrombosis of the large veins of the bitten limb had occurred.

**Malarial or Climatic Neuralgia, and Its Treatment.**—Dr. A. S. Faulkner, of the India medical service (retired), presented a paper with this title, in which he said that the symptoms of the affection, referable especially to the nervous system, were: the regular periodicity of the attacks; acute, if not excruciating pain in the set of nerves implicated (usually the facial), the pain being characterized by being confined only to the one set of nerves but shifting from one nerve to another in that set. At first the pain was accompanied by a slight rise of temperature followed by copious perspiration at the height of the attack, which was indicated when the pain had reached its acutest stage. Palpable throbbing of the arterial system, in connection with the affected nerves, was always evident, and a feeling of nausea or actual vomiting took place. The attacks were followed by marked general depression and subsequent lassitude. Quinine properly administered was a specific in the treatment of such cases.

**The Geographical Distribution of Undulant (Malta) Fever.**—Captain M. Louis Hughes, of the British army medical service, read a paper on this subject. The geographical limitation of the endemic prevalence of this fever appeared to be, he said, primarily a question of temperature. In Europe, north of the annual isotherm of 55° F. (about latitude 46° north) only imported cases were met with, which did not start endemic foci affecting others. South of this line the endemic prevalence of the disease became of increasing importance until we reached the annual isotherm of 60° F., where the disease was found to be firmly established, and especially prevalent in those months during which the mean temperature was at or above 60° F.

**Malarial Eye Affections.**—Major M. T. Jarr, of the British army medical service, read a paper, of which the following is a brief abstract: Conjunctivitis: At least three different varieties of conjunctivitis had been found connected with malaria, viz., (*a*) in-

termittent ophthalmia; (*b*) conjunctival injection due to neuralgia of the fifth cranial nerve; (*c*)) epidemic conjunctivitis.

Keratitis: The forms of keratitis ascribed to malaria were: (*a*) dendritic keratitis; (*b*) keratitis profunda; (*c*) vesicular keratitis (herpes corneæ).

Major Jarr also mentioned a case of iritis, one of cataract, and another of monocular ciliary spasm associated with aphasia, all of which were distinctly malarial in origin.

The section was well attended, and the interest taken in the debates and discussion was most marked. The proceedings terminated with a vote of thanks to Dr. Thin, the president, and to Fleet Surgeon J. Tyndall, R.N., and J. R. S. Robertson, M.B., the honorable secretaries.

(*To be continued.*)

## Correspondence.

### OUR LONDON LETTER.

(From our Special Correspondent.)

MORE ECHOES FROM PORTSMOUTH—THE ADDRESSES—THE SPEAKERS—THE REFORMS—MUSEUM.

London, August 1., 1899.

The Portsmouth holiday is over, and its various delights form the chief topic of conversation with those who have returned. To listen to some of them you would suppose they went only for the excursions and entertainments. But others, as if to neutralize that impression, talk only of the solid work in the sections. Others, again, are full of the addresses and set discussions. If I gather up a few of the impressions made on friends and communicated to me, you can take any contradictory statements as those of different persons.

All seem agreed that the meeting was a success. It was not so numerously attended as last year's gathering, but then the academical attractions of Edinburgh would account for that. The sections were not overcrowded, but good discussions seem to have been held. The arrangements for the press and for visitors were much superior to those of Edinburgh, the names of the speakers being displayed so that any one entering late could see at once what was going on. Of the addresses the president's was by far the most attractive. In fact, Dr. Cousins showed himself to be an exceedingly able speaker, and though he had his notes before him he scarcely ever looked at them. Yet the address was full of facts and figures. Apart from this his genial presence everywhere contributed greatly to the pleasure and success of the meeting. At the dinner he was in great form, and his hospitality every day seemed unbounded. As some one said, his presidency must have cost him "a pretty penny."

The address in medicine is always regarded as an important function. This year it was undertaken by Sir Richard Douglas Powell, whose reputation raised great expectations and attracted a large audience. Unfortunately, his voice was unable to fill the room, and many could not catch a word. Your reporter told me it was most difficult to follow what he said, even in a favorable position. He, however, made an abstract which shows the address was worthy of the occasion. Sir Richard read it all, and leaning over his manuscript of course increased the difficulty of his being heard.

The address in surgery, by Professor Ogston, excited great interest among the military and naval members, inasmuch as it constituted a grave indictment of the department calling for the serious consideration of government. Some of the newspapers have taken up the subject, and are enlightening the public on the danger, in case of war, of the cramped state of the medical services. Professor Ogston is, of course, accustomed to public speaking and able to make himself heard. He was very energetic. The day was oppressively hot, and at one time he paused for a moment to throw off his university gown in which he had commenced the address, no doubt much to his relief and certainly to the amusement of many.

In the section on tropical medicine Dr. Thin made a powerful appeal for the opening of Netley Hospital to those about to practise in the colonies, and went so far as to put his view in the form of a resolution, which, however, the section did not adopt.

At the second general meeting after the address in medicine there was a stampede into the fresh air, only some thirty or forty members remaining to discuss the policy of the journal and the conduct of the council, as well as other subjects of reform. Resolutions, of which notices had been given, were moved, and acrimonious discussions ensued, but no advance was made, and the meeting was adjourned. At the next meeting there was still no time to discuss these resolutions, and some of the proposers were not even present, so that their motions could not be debated.

The museum was located rather unfortunately, the ventilation being imperfect and the heat very oppressive. The usual exhibits were shown, and this advertising department appeared as flourishing as ever.

### LETTER FROM BERLIN.

TUBERCULIN TEST FOR INFECTED COWS NOT INFALLIBLE—MILK STERILIZATION—ANTITOXIN METHODS IN BERLIN.

Berlin, July 24, 1899.

Five years ago, through the courtesy of the director of the Kaiser und Kaiserin Friedrich Kinderkrankenhaus, Professor Baginsky, I was fortunate enough to study the value of antitoxin in diphtheria. Again it is interesting to look back and note the present improvements and changes which experience has made necessary.

Professor Baginsky is essentially a man of painstaking detail in all matters pertaining to the clinical and microscopical and bacteriological diagnosis of diphtheria. In fact, no diagnosis is made *intra vitam* without the use of all known means of securing the same. Thus the objective and if possible subjective symptoms are used as mere guides, and the real crucial tests are secured by utilizing the urine, the blood, fæces, sputum, membranes—in fact, any and all secretions, and, as additional factors, excretions. Professor Baginsky insists on giving due weight and consideration to every point and utilizing every method of combined clinical and laboratory aid to arrive at an intelligent understanding of each case. The fatal termination of a case is the beginning of a real comparison of post-mortem and *intra-vitam* findings. Each and every organ is carefully studied, sections are made and stained, and bacteriological examinations made of the blood found in the heart, spleen, etc., pus, lymph—in fact, any special pathological findings are examined, which means the devoting of such extra means to the end of elucidating all possible points toward the completion of the history of the case.

Berlin in general has different regulations from those of America. Here the public schools will reopen about August 12th, after having been closed since July 12th, so that the children have a vacation of about one month.

I visited the large dairy of Grube, in Victoria Park,

and was favored with a view of one of the largest milk establishments in Germany. All cows are given dry fodder, are kept scrupulously clean, and subjected to a careful tuberculin test. I was very much interested to learn that one large batch of one hundred cows (Swiss breed) was examined with the test, and eighty-five gave positive tuberculin reactions. Further inquiry elicited the following very interesting information, which when I transmitted it to our director, Professor Baginsky, he was not willing to indorse. A great many cows, in fact almost all, react with the tuberculin test "when tubercle is present," but—and here is what I regard as vital—some cows, although tuberculous as proven by a post-mortem, did not show any reaction.

Again: cows that were not tuberculous, *i.e.*, in which no positive evidence of tubercle in the shape of lymphatic glandular swellings could be found, gave very strong reactions; so that we cannot yet absolutely say that none but tuberculous cattle will react.

Another point, and one which it is well to note, is that milk is subjected to much less steaming than formerly. The length of time for this process was from thirty to forty-five minutes; now it has been reduced to ten or fifteen minutes. Experience showed that the albuminoids of milk, and chiefly the casein, were rendered very indigestible, but by reducing the time of steaming they were made more digestible. By subjecting the milk to this reduced time of steaming a great many bacilli, chiefly the "hay bacillus," are not destroyed, but they can be easily killed afterward by "cooling" the milk, and more especially by first cooling it and then putting it on ice.

At the coming "Naturforscher-Versammlung," which takes place at Munich September 18th, the subject of intubation in private practice will come up for discussion, together with a series of questions pertaining to the technique, indications, after-treatment and medication, and dietetic management. It may be of interest to note that, responding to an invitation from Professor Baginsky to contribute my experience, I have given my own from private practice, including a series of consultation cases which I have had since the advent of antitoxin. It is a striking fact, in Germany at least, that never more than now is antitoxin used in the treatment of both mild and severe diphtheria. It is not as it was in former years, and the diphtheria pavilion is not now dreaded. Professor Baginsky's mortality—including cases in which the patients were moribund, virtually doomed before being sent to the hospital, and those that were really hopeless and sent away so that the physician might be spared the odium of a fatal case of diphtheria on his shoulders, and all cases of diphtheria with and without intubation in which operations have been performed—is about nine per cent.; formerly it was above forty per cent.

LOUIS FISCHER, M.D.

**One Hunterian Oration.**—In 1826, Sir Charles Bell describes the Hunterian oration in the following words: "As to the Hunterian oration I know not what is to become of it. It is given in regular succession by the seniors of the college. To-day Sir Anthony Carlyle delivered it. I heard him at the public dinner of the hospital boast what he would do. I saw the moment I entered that he would fail. He had a large volume of manuscript before him, suited to a course of lectures rather than to one discourse; as many shell-fish as you can see in an oyster shop; and he had the folly or the wit to make the oyster the subject of the Hunterian oration. He began with supercilious confidence, and after many interruptions finally broke down after an hour and a quarter's delivery amid the noises and hisses of the audience."

**Contagious Diseases—Weekly Statement.**—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending August 19, 1899:

| | Cases. | Deaths. |
|---|---|---|
| Tuberculosis | 181 | 138 |
| Typhoid fever | 61 | 17 |
| Scarlet fever | 61 | 2 |
| Measles | 106 | 7 |
| Diphtheria | 136 | 25 |
| Laryngeal diphtheria (croup) | 7 | 5 |
| Cerebro-spinal meningitis | 0 | 6 |
| Chicken-pox | 5 | 0 |

**Hygiene in Florence.**—A writer in the London *Morning Post* writes as follows concerning the unhygienic state of Florence: "Having been detained by illness in Florence, I feel it is a duty to English visitors to this most glorious city, 'the City of Flowers,' to make known its sanitary condition, which can only be described as pestilential. There is no wholesome drinking-water and there are no drains. There is a most unsatisfactory system of cesspools for each house, and these are emptied at mid-day by carts, the effluvium of which is hardly to be imagined. Even as I now write I have to keep the windows closed, as there is an array of these disgusting carts engaged on two houses opposite. Fevers and other diseases occur daily in consequence of the existing state of things. Yet the educated Italians allow this condition of affairs to continue. We have heard lately of great changes contemplated, but reforms are not made. No visitors should enter the city without knowing the risk they run. I trust I may be the means of saving others from my own unfortunate experience."

**Health Reports.**—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended August 18, 1899:

SMALLPOX—UNITED STATES.

| | | Cases. | Deaths. |
|---|---|---|---|

### PSYCHOTHERAPY; OR, SUGGESTION AS A CAUSE AND CURE OF DISEASE.[1]

BY H. H. SEELYE, M.A., M.D.,

PRESIDENT HAMPSHIRE DISTRICT MEDICAL SOCIETY; VICE-PRESIDENT EX OFFICIO MASSACHUSETTS MEDICAL SOCIETY.

CONFORMING to the established custom in our society gatherings, of reading papers on subjects that have particularly interested or engaged the attention of the writer, I have determined to touch upon a branch of medical science which seems to me, as a rule, to receive too little consideration from the busy practitioner in his routine work. This is the part that suggestion plays as a causative and curative agent in disease.

I desire here to state expressly that I do not mean to discuss the broad subject of hypnotism as generally understood, but rather the outlying field of influences acting on the mind when no conscious abnormal change has been produced in the patient. I choose to confine my remarks to this limited sphere, because of the frequent opportunities for observation of its phenomena in my own experience, while I have never seen occasion nor felt the necessity for the application of complete hypnosis.

Before proceeding further in this discussion, it will be necessary to elucidate to some extent what may be considered to be the essential difference between mere suggestion and true hypnosis. Hypnotism depends largely on suggestion, and by some, especially the disciples of Liébault and Bernheim representing the Nancy school, it is supposed to be the only essential element in inducing the state. But in hypnotism there is the conscious and free subjection of the will and all the mental and physiological functions of the subject to the desires of the hypnotizer. Hence it is frequently asserted that a person cannot be hypnotized unconsciously or against his will. Suggestion, on the other hand, may frequently, and altogether unconsciously, play its part in producing symptoms or modifying bodily functions, without the patient, or even sometimes the operator, being in the least aware that any unusual or unperceived forces are at work. Again, in hypnosis there is such complete surrender of the subject's personality, that he is unable to resist performing any act suggested, whether it is to be carried out immediately or performed automatically in the future, when apparently freed from the operator's influence, that is, in the so-called "post-hypnotic" state; while suggestion, on the other hand, may be accepted or rejected at the will of the subject, and is most apt to work successfully if the patient is unaware that the suggestion has been intentionally made with the expectation of a given result. Thus appropriate ideas, artfully suggested, will often arouse the latent subconscious mind to perform wonders in undoing disorders wholly or partly caused or aggravated by unconscious fears or anticipated evils.

[1] President's address read at the annual meeting of the Hampshire County Branch of the Massachusetts Medical Society, at Northampton, Mass., May 11, 1899.

For the purpose of explaining the possible mode of action of suggestion, hypnotism, and allied phenomena, modern psychology has propounded the tentative working hypothesis of our possessing a sort of double personality, acting on and through the brain and nervous system. These two personalities, living in harmony and usually working in unison, and acting and reacting on each other, may be designated as the conscious, and the subconscious or subliminal; or as the objective or physical, and the subjective or hidden and immaterial mind. The objective or conscious personality is the one we are all so well acquainted with, and is, in our waking hours, acutely responsive to all outside influences, as well as to ideas mentally conceived, and receives impressions and transmits impulses in accordance with the conscious will of the individual. But the subjective personality and subconscious mind work unobtrusively and incessantly, through both our waking and sleeping hours, and are at all times in a state of receptivity to influences exerted through the senses from the world without, and presumably also to less material forces and impulses originated in, or transmitted through, the physical brain cells and nervous ganglia. It is this form of mental activity that is manifested in dreams and in the vagaries of the somnambulist, that enables us to awake at a stipulated hour, and that recalls names and facts we vainly strive to remember, but that suddenly come to us later on when thinking about something else. It is this same power which, with no conscious thought or effort on our part, regulates the involuntary functions of breathing, heart action, digestion, and the automatic activities of all the bodily organs. While responsive to stimuli from the conscious physical personality, it on the other hand often directs or modifies the ideas and actions of the latter. It is as though there were two individuals of similar temperaments living as neighbors in the same house, at times working apart, and at others in harmony together. Each may do things and know of matters concealed from the other, but each may call upon the other for assistance when required. Each attends to its own affairs, but at times seems to delight in befooling or deceiving the other, or in acting eccentrically, to the surprise and wonder of its neighbor. While co-workers in the general management of the house, viz., the body, each works in its own way and as suits its own pleasure.

It is by recognizing this hypothetical interrelation of two personalities in one individual, that we can explain most of the phenomena induced by suggestion. An idea becomes implanted in the mind by either a known or an unknown process, and there it is taken up by the subconscious personality, and worked over and developed, till its effects appear in some easily recognized results, involving, it may be, some part of the body or its functions. Conviction or belief that a certain effect is to follow a given act is helpful and conducive to this unconscious transformation, but conscious belief is not always essential, provided that the subconscious ego is convinced, and so stimulated to activity. Thus many of the physiological, pathological, and curative phenomena we so frequently observe, and which at times seem almost inexplicable, may be accounted for by alterations of metabolism and nutrition produced by

the subconscious expectations aroused by suggestion. For instance an ignorant child is told to work some ridiculous charm on a wart, and after a time, to his astonishment, he notices that it is gradually disappearing, though he has consciously given little or no attention to the matter since the first. But the subconscious personality, easily convinced of the efficacy of the act, has been steadily at work, concentrating energy and modifying nutrition in the diseased epithelial cells, till the cure is wrought. On the other hand, a small benign growth may appear in a woman's breast, on the face, or elsewhere, and soon the idea of possible malignancy suggests itself. Without getting skilled advice the patient keeps the matter to herself, broods over it, and watches its progress, and the result here likewise is increased stimulation of the morbid process already begun; expectation and fear result in realization, and at last true malignancy develops.

These are examples of the often-noticed effects of the mind on the body. Conversely the physical condition reacts as markedly on the mind; and the man, as a whole, is healthy and well balanced only when a sound mind inhabits a sound body. Thus, if one is subject to attacks of indigestion, sluggish bowels, or biliousness, the effect is mental despondency and low spirits; if the body is weary from overwork, the mind is paralyzed and demands sleep. If it rains or storms, the nervous system reacts to it, and we are cross or depressed. If the sun shines and the birds sing, and all nature seems glad, we are happy and rejoice with her. So, when the influence of the subconscious mind is dominant, it affects the bodily functions for better or worse, and when, on the contrary, the physical and material personality asserts itself preeminently, the spiritual subconscious individuality appears almost dormant. Hence it is that the high-strung, nervous, mentally developed man of genius often lacks in physical development; and, on the other hand, the man whose brutal or animal parts are predominant rarely experiences the inward light and mental illumination of the spiritually inclined scholar.

While essaying thus a plausible explanation of the manner in which suggestion may produce its effects on the mind and body of the patient, my main object is rather to draw renewed attention to the many ways in which this power often acts, or may be induced to act, to the advantage or detriment of the sufferer. The essential fact for success seems to be, that either consciously or unconsciously, there must be in the mind of the individual a desire, a longing, a hope, a faith, or an expectation, that a certain condition will in time prevail. Surprising as it may seem, it is however the unconscious belief, usually, that works most powerfully, and often this is directly contrary to the conscious and expressed opinion of the subject. And here suggestion may be made either to strengthen or weaken this subconscious impression, as directed by the operator, for the good of the patient. Granting this theory of unconscious cerebration and expectant attention, due to suggestion, to be correct, we have now an adequate explanation of the many authentic cures of both functional and chronic organic disorders wrought by homœopathists, osteopathists, hydropathists, electropathists, masseurs, faith curers, Christian scientists, religious enthusiasts, blue-glass cranks, and by all the other fads that from time to time rage and flourish successfully for a while, only to give way at last to some other new and wonderful method of cure. While not belittling the real value of the many rational scientific uses of active drugs and sanitary and hygienic measures, I desire especially to emphasize the added therapeutic value of the mental attitude of the patient toward the physician and his curative measures, as a very important item in the rapidity and thoroughness of the cure. Every observant doctor must have had his own experiences confirmatory of this fact, and it remains for me only to relate a few instances in my own practice illustrating the truth of this hypothesis.

Case I.—Gracie J—— was a young girl of eighteen years, of delicate nervous temperament, earning her own living by work in a hat factory. Her general health was good. One day, while suffering from a headache, she bought at a drug store some so-called "headache powders," knowing nothing of their composition, which was probably chiefly acetanilid. At bed-time she took one, and retired for the night. She was soon relieved and fell asleep. In the morning, at the usual waking hour, her girl room-mate found her still soundly sleeping: and fearing the stupefying effect of the unknown powder she tried to arouse her, which, after some effort and with fright expressed in her voice and manner, she soon succeeded in doing. Gracie opened her eyes in surprise at this unusual method of waking, and doubtless noting at once the frightened expression of her companion and her startled cry of, "What's the matter with you, Gracie? Can't you speak?" she seemed forthwith to become literally paralyzed with fear, and found herself unable to move hand or foot, or to utter a word. Her room-mate's added fright and startling announcement that the powder had poisoned her and she was certainly paralyzed, and the summoning of the rest of the excited household, only added to the intensity of the girl's belief in the actuality of her helpless condition. Fuel was added to the flames when a hasty summons brought to her bedside a local homœopathist, who assured the family that the effects were due to the powder, which he later, on analysis, found to be an active poison. In his anxiety and ignorance of the true nature of the case, he visited the girl nearly every hour throughout that day, with the natural result that she remained in the same condition, and the family and friends became discouraged, and wished for a change of doctors. Having been summoned about 6 P.M., I found the room full of anxious friends watching the girl, who was acutely awake and mentally active, but lying flat on her back unable to talk, swallow, or use any muscles save those of the eye, which, you will remember, she had found responsive at the moment of waking, before becoming aware of the paralysis. Could suggestion have been more artfully employed for evil than here? Knowing that there was no pathological condition that could produce such an assemblage of symptoms, it took but a moment of observation and reasoning for me to divine the true state of affairs, and to commence the cure by the use of counter-suggestion. So, after requesting the family to withdraw for a few minutes, I explained confidently to the patient that the reason of her remaining in her present condition was a failure on the part of the homœopathist to recognize the cause of the symptoms and to apply the proper remedies, but that, understanding thoroughly her disorder, I could assure her of a prompt and rapid recovery. Then, having gained her confidence, I began using remedial measures in themselves inert, applying them, and at the same time so commenting on them as to attract her attention to, and concentrate her nervous energy on, successive paralyzed parts; till in turn she speedily recovered her voice, was able to swallow, moved her head, then her hands, arms, legs, and body, and in less than five minutes from beginning counter-suggestion she was walking about the room and out into the hall, shouting to the astonished family that she was cured and all right. There was soon restored confidence in her ability to use all her natural powers, and a call from me the next morning showed no farther need of my services than a prescription for a general tonic, as a future "brace-up." The cure was wrought entirely by suggestion, without the patient's being at

all aware of the efficient cause of her recovery, which she, as intended by me, attributed to the intelligent use of very powerful drugs and local applications. To the query, what would have happened in this case had it been persistently treated homœopathically or otherwise under a continually erroneous diagnosis, I will say I believe that, finding soon that she was not really dying, and believing thoroughly in the efficacy of the small, frequently repeated doses administered, her attention would undoubtedly have been kept constantly, but unconsciously, fixed on the expectation of an ultimate cure, and so after a time there would have been a slow but steady and sure recovery, to the gratification of the patient, the glory of the attending physician, and the fattening of his pocketbook.

Certain features in the above case make prominent three facts to which I wish to direct your attention. First, the power of suggestion in causing as well as in curing disease. Second, the proneness of physicians to overlook or ignore suggestive influences as possible causes or factors in producing symptoms. Third, the fallacy of always attributing any unusual or unexpected complications to the good or ill effects of the remedy last administered.

Case II.—This is illustrative of the successful methods of the Christian Scientists, faith curers, osteopathists, and that class of fakes. Mr. C. P——, twenty-eight years of age, a farm laborer, came one day to my office with his head drawn around to one side and bent down toward the shoulder, and complaining that he had awakened that morning with intense pain and lameness in the muscles on that side of his neck at every effort to turn his head the other way. He also said, that he had once before had just such an attack, and was under treatment for two weeks before he was relieved and able to go to work. It proved to be a typical case of wry neck. I asked him if he would be surprised if I should send him from my office cured after a few minutes of treatment. This aroused his attention and credulity, and he laughingly replied that he did not think I could. I assured him, however, of prompt relief, and began making local applications and rubbings, which I told him would draw the pain out and scatter it. At the same time I encouraged him to move his head first slowly, and then violently, remarking constantly that the pain was lessening; till, within five minutes he found he could turn and twist his head as freely as ever, in any direction, without the slightest pain. The Christian Scientists would, in time, have produced the same effect, by telling him that pain does not exist, it is purely subjective and immaterial, and if you thoroughly believe in its non-existence you can feel none. The fact, however, really is, that the subconscious, subjective personality can be, and is, easily deceived, and as readily convinced by suggestion, even against the reason and the expressed belief of the conscious self.

Case III. was of a similar character, except that the motor, rather than the sensory, nerves were affected. A refined lady aged about twenty-eight years, a professor's wife, called at my office one forenoon, bemoaning the sudden loss of her voice, which she particularly desired to have the use of that evening, as she was to receive at a students' promenade concert. She had been exposed to a draught the previous day and had developed a slight laryngitis. She could not speak above a whisper. I encouraged her to expect immediate relief, and assured her of the powerful efficacy of a harmless application which I made externally over the region of the vocal cords. I, in a few minutes, had the satisfaction of hearing her speak in her usual tone of voice, as she talked with me, even when I purposely withdrew to an adjoining room. She had no return of the difficulty, and conversed fluently and easily all that evening. In this case there was a passive relaxation of the vocal cords, which required the stimulus of an increased exertion of nervous energy to restore their tone, and the measures I employed merely aroused, subconsciously, the vital forces and focussed them on the refractory organ.

Case IV.—While spending a summer vacation at one of a group of hotels on the shore of a lake in northern New York, I was summoned one evening to a neighboring hotel to see a young man aged twenty-five years, a guest, who was said to be suffering from the effects of a sunstroke. He had been lying out that afternoon, with the thermometer in the nineties, under the shade of a tree. On returning to the house he had complained of an intense headache. Soon after he fell unconscious, and then began to have violent spasms, requiring the united strength of half a dozen men to hold him and keep him from injuring himself. He continued to be at times delirious, and then for a while apparently comatose, and again the spasms would recur. A young medical student, who was supposed to be the only physician in the neighborhood, worked over him for several hours, with no amelioration of the symptoms. Finally some one spoke of the presence of a doctor in an adjacent hotel, and I was sent for. After a hasty consideration of the history, surroundings, and symptoms of the case, I arrived at the diagnosis of acute cerebral hyperæmia from heat prostration, giving rise to fear of sunstroke; the symptoms of which the subconscious personality proceeded to imitate to the best of its knowledge and belief. In other words, the condition was what is usually designated as acute hysteria from fright. By at once assuming a confident attitude, and assuring the bystanders, in the hearing and for the benefit of the apparently unconscious patient, that there was no danger and he would soon be all right again, I proceeded to suggest, through my talk with them, the course and sequence which the symptoms would immediately take. Strengthening these impressions by the use of measures in themselves inoperative but asserted to be most energetic, I in a few minutes was able to arouse the patient, quiet his excitement, restore his reason and his powers of co-ordination, and to see him walk upstairs to his room, and soon after fall into a quiet, normal sleep, from which he awoke the next morning well, and little the worse for his experience. Had the mental element in this case remained unsuspected, and the man been left to himself, the object of a frightened but sympathetic crowd of guests, the spasmodic movements and hysterical excitement, with alternating periods of coma, would doubtless have lasted till the sufferer's nervous energies had become completely exhausted, and a long illness might have ensued. In biblical times he would have been said to have been "possessed with a devil," which was at last "cast out" miraculously.

Case V.—This was an illustration of a persistent impression inducing a patient to believe in the existence of a disease which, unbeknown to him, may have been for a long while cured. J. B——, aged fifteen years, a schoolboy, refined and intelligent, had an attack of acute inflammatory rheumatism, with fever, and swelling in the arms and legs, which gradually improved under treatment with the salicylates. After a week or so the symptoms had nearly disappeared except a slight lameness in the right ankle, and he was so far recovered that I ceased to visit him, and dismissed him from my mind. About a month later I met his mother on the street, and inquired if J. was well and again attending school. I was surprised to learn that he had not yet been out of the house, but that the pain in the right ankle had persisted and gradually grown worse, so that for the past two or three weeks he had been limping about with the aid of a crutch. I at once called to see him, and found

him unable to set his foot to the floor and put any weight upon it without wincing, and entirely unwilling to trust it in walking. Examination showed no swelling or local tenderness, and I found I could manipulate the foot in ways that would have been very painful had there been any real inflammation in the joint. I was therefore forced to the conclusion that the pain was entirely subjective, and due to the timidity of the patient and his belief in its reality and persistency. By suggesting its prompt dissipation, as a result of local applications and supposedly skilful massage, I was enabled within five minutes to present him to his mother cured, free from pain, dancing, hopping, running, and laughingly assuring her that he should have no further use for his crutch. He has never since had a twinge of rheumatism. The next day he was out of doors, and on the following day returned to his school duties. Could professional masseurs have done better, and do not many of their remarkable cures owe their success largely to the suggested belief in the efficiency of the agent so confidently and energetically employed?

Case VI. well illustrates the vagaries of the neurotic or hysterical temperament. A little girl, A. C——, nine years of age, living about five miles away in the country, was attacked with symptoms leading her medical attendant, since deceased, to suspect infantile paralysis, or some unrecognizable organic spinal disease. From the waist down she gradually became paralyzed, and after losing the power of her feet and legs the bowels became sluggish, and the bladder ceased to act, so that catheterization became necessary. The child had been confined to the bed for several days when I was called in consultation. After a brief study of the symptoms and an examination of the reflexes, and assuring myself of the normal action of the kidneys, I came to the conclusion that here fear and suggestion had been at work, and the doctor's solicitude in watching for the progressive symptoms of paresis had induced subconsciously the very condition expected and feared. With the permission of the attending physician I at once began to invoke the assistance of counter-suggestion, and after gaining the confidence of the little patient it took but a few minutes of energetic manipulations and assurances of relief to have her out of bed, make her empty her bladder voluntarily, rush out of the room to her parents, who greeted her with the cry, "A miracle, a miracle!" and then run a foot-race with her little brother out of doors. Less than ten minutes' suggestion had sufficed to remove permanently all symptoms of the dreaded disease. The old doctor was nearly as much astounded as were the family and friends, and could scarcely induce himself to believe in the actuality of the cure; and for some time after he continued his solicitous attentions and visits, to the detriment, but not serious relapse, of the patient.

Now comes the sequel! Ten years after these events, I was summoned by another physician to see in consultation a young lady of nineteen years, living in the same vicinity. I failed to recognize the house, family, or young woman, as old acquaintances. She had been suffering for a number of weeks from an irritable stomach, and finally she could retain no food, but vomited persistently mucus, bile, and blood. For some days past she had been unable to retain even a swallow of water. Ulcer of the stomach seemed the logical and accepted diagnosis. While examining the patient she remarked to me that I had doctored her once before, ten years ago, and asked if I did not remember the little girl I cured of paralysis. In an instant the case took on a new light, and its cause and treatment flashed upon my mind with the force of conviction. I had often read of hysterical vomiting, even of blood. And here it was! If suggestion worked so efficiently ten years before in the cure of the girl, would it not act equally well here in the woman? After explaining my belief to the attending physician, with his assent I placed a few drops of a placebo in her mouth, assuring her that in a few moments she would find her stomach in a retentive state. Soon a swallow of water was taken and retained, and then the first bit of bread or solid food she had eaten for many days. We waited half an hour for it to come up. But suggestion had won the day, and for some time after she ate quite freely and retained everything. For future treatment I recommended that the doctor should employ only tonics, with the aid of so much suggestion as his self-confidence would warrant him in employing. After a period of improvement, however, his faith and courage, and her confidence in him, gradually waned, and she at last relapsed into chronic invalidism, and he became disheartened and left her to her fate. This was pre-eminently a case for the so-called "mind curers," and for them alone. Who will say that the sect is not endurable, if they could be made to confine their method of treatment to its proper sphere?

Case VII., and the following one, are examples of a class of patients that I frequently encountered, though usually with less marked symptoms, during my eighteen months' hospital service in New York, before entering upon private practice. Early in my professional career I became impressed by the great influence exerted by the interrelations of the mind and the body, and subsequent experiences have in no degree lessened these convictions. In both of these cases not only the voluntary, but some of the involuntary functions as well, seemed susceptible of modification by suggestion.

The patient, Hannah B——, aged thirty years, was brought in an ambulance to the hospital about five o'clock one afternoon, without any history. She was comatose, totally insensible to all stimuli, breathing stertorous, heart action feeble, with pulmonary œdema well developed, and convulsions occurring every three or four minutes. The bladder was emptied by the catheter of one pint of normal urine, and physical examination revealed no lesion of any organ. Her temperature was normal. On the whole, the picture presented was that of a moribund case of acute uræmia. As everything taken into the stomach was immediately vomited, stimulants, sudorifics, antispasmodics, and cathartics were freely administered subcutaneously and by rectum, with inhalations of chloroform during the convulsions, and she was cupped and poulticed, while perspiration was further encouraged by packing in wet hot blankets. For a period of several hours of constant medical attendance there was no appreciable improvement, but toward midnight she became more quiet and slept naturally, so that from that time till morning she was left to the care of the nurses. The two following days she seemed convalescent and required little attention. While making my regular morning rounds on the third day, knowing now that she had no kidney lesion, and having been assured by the nurse that she was doing well, on coming to her bed I merely asked a few questions and made a rather superficial examination, and was about to pass on, when she called me back and began a long story of symptoms and ailments to which I had no time to listen; so, ordering a mustard paste to be at once applied over the chest, I abruptly withdrew. This apparent lack of attention seems to have provoked her, and when a few minutes later the mustard began to draw and the nurse positively refused her request to remove it, she became quite angry and rebellious. The result was, that before I had left the ward the nurse hastily approached me and informed me that H. B—— seemed to be dying. On crossing over to her bed I was, to say the least, surprised to see the patient in almost

precisely the same condition as when she had been brought to the hospital. To the experienced eyes of three doctors and three trained nurses present, she seemed undoubtedly in a dying condition. She could not be aroused, was insensible to pain from pin-pricks or pinching; the reflexes were abolished, the heart action was feeble, the respirations were rapid, and, most remarkable of all, there was unmistakable and pronounced pulmonary œdema, large and small mucous râles being plainly audible throughout both lungs. I was momentarily dumfounded, and racked my brain to recall any known disease or disorder that could produce such an array of alarming symptoms in a person ten minutes before seemingly in comfortable health. Urinary examination had excluded uræmia, and there was no one-sided paralysis, with irregular pupils, nor drawing of the facial muscles as in apoplexy. Hysteria at once forced its claims upon me; and although I had never read or heard of a case in which not only the voluntary but also the involuntary functions had been so quickly and so profoundly modified, I became convinced that this was the actual explanation of her condition. Her chagrin and anger at the slight attention paid to her complaints by the doctor and nurse had produced so great a mental revulsion as to throw her off her balance, and to place her completely under the sway of the subconscious *ego*. Feeling now sure of my diagnosis, I determined to use counter-suggestion in a most active form; and believing that, while the functions of the objective personality were in temporary abeyance, the subjective individual was acutely awake and responsive to outside impressions, I appealed to its attention by ostensibly directing all my suggestive remarks, not to the patient, but to the neighboring doctors and nurses. I sent one of them for a harmless remedy, which I began using with apparent caution in minute doses, meanwhile assuring the attendants, with a warning sign, that it was a most powerful drug, and that within five minutes the patient would either be dead or well on the way to recovery. Then speaking confidently, I observed that the eyes would first open, then the mouth would move and consciousness return, next the use of her hands, arms, legs, and voice would follow, in never-failing succession, and that the œdema would gradually clear up and the pulse become stronger; and as these effects promptly followed each suggestion, by encouraging the now conscious and surprised patient to use her various muscles, as the danger was now passed, I succeeded within five minutes from the beginning of this mental treatment in restoring her to a perfectly normal condition, to the astonishment of all concerned as well as myself. It had taken from seven to eight hours of active medication, two days before, to bring about no better results than were here duplicated by a few moments of suggestive therapeutics.

Case VIII.—The final specific case I will mention has several points in common with the last, and occurred some time later in the same hospital ward. Mary W——, twenty-three years of age, was brought by an ambulance from a tenement-house with no history, but suffering from a sore throat and great hoarseness, coupled with some apparent obstruction in the larynx, interfering with free respiration. She was too weak and voiceless to give any account of herself. Her respirations were rapid and labored, and the air passing through the narrow laryngeal opening whistled as in a severe case of membranous croup. There was no fever, nor, except for this obstruction and slightly swollen submaxillary and cervical glands, any other bad symptom. After admission the respiration gradually grew more and more difficult, till we began to be alarmed. Our visiting physician, and later the reputed best diagnostician in the city, were called in. Examination of the larynx showed them nothing but a congested, narrowed, and spasmodically closed orifice. There was a difference of opinion among the consultants as to whether it was a case of true croup, or merely the spasmodic form of acute laryngitis. About noon, as the diagnosis was in doubt, and membranous croup, being a contagious disease, was not allowed admission to that hospital, I notified the city board of health. Soon after two of its medical members appeared, and, while hedging as to diagnosis, permitted us to retain and treat the case in that ward. As the day advanced, and treatment by counter-irritation, hot applications, and inhalations of chloroform and steam from the croup kettle, with such internal medication as was indicated, produced no improvement, and as the patient gradually became unconscious and cyanotic, the only chance for life, as a last resort, seemed to be an operation for tracheotomy. This I was authorized to perform if at any time during the ensuing night a crisis seemed imminent. As midnight approached the patient seemed comatose and about to expire. I summoned the hospital staff in consultation, and it was decided to operate immediately. During the preparation of instruments and dressings, the dangers of the operation and chances of recovery had been freely discussed, in the presence of the patient, by the six or eight doctors and nurses attending. Then, standing at her head, I made my first incision through the skin over the thyroid cartilage. As the knife blade cut into her, I noticed a slight twitching of the girl's eyelids and an almost imperceptible wincing, as if she felt and feared the cutting process. A second attempt to expose the subcutaneous tissue was accompanied by a slightly more pronounced movement of shrinking. At once dropping the scalpel, I quietly remarked to the onlookers that I had just learned something new about this case, and I believed I could produce a more prompt and satisfactory cure by other means than an operation. Then asking for a powerful faradic battery, with the aim of bringing suggestion to play on the subconscious mind of the patient without her suspecting it in the least, I went on to describe how I had found evidence that there was here merely an obstinate spasmodic contraction of the laryngeal muscles, which would doubtless quickly yield to the external application of electricity with a violent jerky making and breaking of the current. I then began to move the electrodes about, over and on opposite sides of the larynx, constantly increasing the intensity of the electrical action, and causing irregular but strong contractions and relaxations of the cervical muscles. I soon called their attention to the fact that the laryngeal spasm was relaxing, the whistling sound becoming less marked, the respirations slower, deeper, and easier, the eyes were opening and consciousness returning, while vocal sounds were becoming possible. And as coincidently with these suggestions the patient aroused and struggled to get away from the annoying application, I was unrelenting in my punishment, and increased its severity, till she audibly begged me to desist, assuring me that she now felt perfectly well, and surprised at her unfamiliar surroundings.

We found later that this young woman had been a frequent inmate of other hospitals, and our conclusion was that she had taken advantage of her opportunity, at some time, to observe a case of membranous croup, the symptoms of which she unconsciously reproduced while suffering from a so-called hysterical attack. And it was only when fear of actual death or some great deformity had powerfully appealed to the subconscious personality, that the malevolent power was relaxed, and it was finally inveigled to believe in the truth of statements, however absurd, suggested by one whose authority and methods it had learned to respect.

Having now endeavored to entertain you with the relation of a few of the most typical cases that have come under my own observation, in which the power of

suggestion, intelligently and almost exclusively used, has produced remarkable physiological, pathological, and therapeutical results, it would seem unnecessary to attempt further to strengthen my thesis by referring to the many other ailments such as headache, neuralgia, insomnia, indigestion, chorea, neurasthenia, hysteria, hypochondria, insanity, and certain minor surgical operations, that may be alleviated, arrested, or hastened to a cure by the rational employment of this influence as an adjuvant to our drugs and other well-recognized modes of treatment. For while cases are comparatively rare in which purely suggestive treatment alone is desirable or sufficient, yet it can almost invariably be advantageously employed, to a greater or less degree, to aid and increase the effectiveness of those older and better-established methods of cure on which we are so accustomed to rely. If, then, this recital of personal experiences shall stimulate some to a freer recognition of the part suggestion unconsciously plays in causing and aggravating diseased conditions, and shall invite them to the faithful and conscientious employment of all the healing powers with which nature has endowed us, the object of this hour's imposition on your attention will have been achieved.

## THE ETIOLOGY OF SCARLET FEVER.[1]

By W. J. CLASS, M.D.,
CHICAGO, ILL.

Numerous efforts have been made in recent years to discover the specific causative factor of scarlet fever. The most notable experiments along this line were those of Crajkowski, Klein, and Edington. Klein in a large number of cases isolated a streptococcus which he regarded as the causative factor; this germ is also considered by a number of French observers to be the cause of scarlet fever. Crajkowski in 1895 reported that he found, in fifteen cases in which he examined the blood of scarlet-fever patients, a diplococcus present in comparatively small numbers. This diplococcus does not stain by Gram's method, and in general stains feebly, and quickly loses its color. Cultures were obtained in bouillon and upon solid media, but not on gelatin. The development is said to be slow and the colonies resemble small drops of dew, not more than one-third to one-half millimetre in diameter. It is pathogenic for mice but not for rabbits. Crajkowski does not claim that the etiological relation of this diplococcus to scarlet fever has been demonstrated. Edington isolated a number of microorganisms from the scales of scarlet-fever patients, among them a coccus which he named micrococcus capsaformis and a bacillus which he considered the specific organism of the disease. Numerous other germs, mostly bacilli, have been described as occurring in the scales of scarlet-fever patients, but their relationship to the disease has never been satisfactorily proven. In this connection a report by Behla published in the *Centralblatt fur Bacteriologie* interested me particularly; Behla did not describe any germ, but he noticed that some pigs belonging to a peasant, in whose family there were several typical cases of scarlatina, developed a scarlet rash. In order to see whether there was any connection between the scarlet fever in the peasant's family and the rash in the pigs, Behla took some blood from one of the children having scarlet fever and inoculated a healthy pig with it, after a few days a scarlet rash appeared around the edges of the inoculation wound, followed by desquamation.

During the winter of 1897–98 the writer had occasion to examine a large number of cultures taken from the throats of persons suffering from various forms of angina. These cultures, numbering from seven hundred to eight hundred during the winter, were grown on blood serum. On examining them I noticed that about every twentieth culture showed large diplococci mixed with the other germs present. During the early part of the winter I did not pay any particular attention to them, but toward spring I began to notice that they were most often present in the cultures taken from patients having scarlet fever. During the following summer my time was occupied by other work, and as there were comparatively few cultures to be examined, I dropped the matter temporarily. Last autumn the germ again showed itself in the cultures and in an increasing percentage of the total number examined. I now began making cultures from the scales of scarlet-fever patients on blood serum, but without any very satisfactory results. The same germ which had been noticed in the throat cultures appeared, but I could not isolate it and it did not appear to be constantly present. I have subsequently discovered that it was constantly present, but on account of its polymorphous character it appeared to be a different organism. As I had been experimenting for the last two years with a culture medium composed of glycerin agar, to which about five per cent. of sterilized garden soil had been added, the thought occurred to me that perhaps the results would be better with this medium. And from the results of my experiments in cultivating scales, throat secretions, and blood from scarlet-fever patients on this medium, I arrived at the conclusion that the germ which I am about to describe was probably the specific causative factor of the disease.

**Morphology.**—A diplococcus, polymorphous in character but resembling, as ordinarily seen in slides made from fresh cultures grown on my medium, a very large gonococcus. This biscuit-shaped appearance is best seen in specimens that have been but lightly stained. Tetrads are frequently seen, and probably they denote the beginning division of the organism. In very old cultures grown under favorable conditions it shows as an enormous coccus having a slightly cupped appearance, the dividing line between the two portions of which it is composed being very indistinct in the more deeply stained specimens. By the division of the large diplococcus a number of smaller organisms are formed, which group together and do not appear as diplococci during the very early stages of their growth. In young cultures grown from the blood of a scarlet-fever patient this germ is often seen as a diplococcus, both segments of which are globular. Streptococcus forms are occasionally, though rarely, met with. Usually, unless in spreading the culture on the slide it is rubbed very hard, these cocci occur in bunches of from ten to fifty, which bunching is due to the large amount of glutinous intercellular substance by which they are united. The organism has no capsule, although at one period of its growth it has the appearance of having one, does not show any spores, has no flagella, and examined by the hanging-drop method does not show any independent motion.

**Staining.**—Specimens derived from pure cultures were stained with a number of the aniline stains. With a watery solution of methylene blue very pretty pictures were obtained, especially when only lightly stained. Carbol fuchsin also stains the microorganism well and brings out its characteristics. It also stains with Bismarck brown and Pitfield's flagella stain. Certain of the organisms do not stain so deeply as others, however, some not taking the stain at all. These organisms when found in blood slides are probably the ones that have been described as protozoa by certain investigators. They are decolorized by Gram's stain, though

[1] Read before the section on state medicine, American Medical Association, June, 1899.

not to the same extent as the gonococcus, the larger variety of the germ holding the stain better than the smaller.

**Biological Characters.**—The culture medium on which this germ grows by preference is, as before stated, glycerin agar-agar to which about five per cent. by weight of black garden earth has been added, the medium being rendered sterile by discontinuous heating. On this medium the scales from a scarlet-fever patient are placed with a sterile platinum loop, and the tubes put in an incubator, the temperature of which is kept at about 35° C. In from forty-eight hours to one week small, whitish-gray, semi-transparent colonies will appear along the track of inoculation and around the scale. These colonies are isolated at first, but subsequently coalesce. Their diameter varies somewhat, but in general is about 1 mm. On taking up some of the material of which the colony is composed, with a platinum needle, it is seen to be glutinous, being drawn out in threads like glue. If the culture medium is dry, or if the colonies are old, they lose their viscidity and become darker in color. On blood serum there is a growth, but it is more meagre than on the earth agar, which is especially adapted for growing the germ from the scales and throat secretions; for blood cultures the serum will do almost as well, as no other organisms are present. Respecting the cultures grown from the blood I wish to state that those taken on the first day of the disease as a rule grow fairly well, whereas later in the disease the growth becomes more meagre, so that without a very careful inspection of the culture no growth is apparent. However, on running a sterile platinum loop over the surface of the medium and making an examination of the material adhering to it, the germ will be found present. Depending upon the severity of the disease, it is sometimes necessary to inoculate more than one tube in order to obtain a growth. The poor growth of the blood cultures obtained in the later periods of the disease is in my opinion due to the inhibitory action of the scarlet-fever blood. As an illustration that this theory is plausible I would refer to Widal's test and to Nuttal's experiments. This inhibitory action of the blood on the growth of the germ suggests the presence in the blood of a germicidal and probably also an antitoxic principle, which, to judge from certain experiments that the writer has made, seems to be the case.

On glycerin agar, to which phosphates have been added, it grows feebly and does not show its characteristic features, which caused me to believe for a time that the growth on this medium was due to a contamination. On gelatin I have not been able to obtain any growth. Milk is not affected by these organisms, although they apparently multiply in it. The germ described has been cultivated from the scales in seventy-four cases of typical scarlatina, from the throats in about fifty cases of angina accompanying scarlatina, and from the blood in twenty-two cases of scarlatina.

**Control Experiments.**—(1) In order to ascertain whether the germ was present in the throats of persons who had not to their knowledge been exposed to scarlet fever, I examined thirty-six cultures taken from the throats of as many different persons. The diplococcus was found in eight specimens, but only in very small numbers, while in the angina of scarlet fever it was invariably present in great numbers.

(2) The thought occurred to me that the germ might be a normal inhabitant of the human skin; to eliminate this point I examined scales from twenty-three persons not afflicted with the disease, the scales being mostly those of dandruff, with the result of finding the organism present in three instances.

(3) Examination of the blood of ten persons in a healthy condition, the blood being taken with the same precautions as those observed in collecting it from the scarlet-fever patients, gave an absolutely negative result so far as any growth was concerned.

**Pathogenesis.**—Rabbits and guinea-pigs in good condition were inoculated by subcutaneous injection of a pure culture, by scarification and inoculation of the wounds, and by injection into the abdominal cavity, without producing the slightest results. The negative results of the subcutaneous injections show that the germ is no pus producer, at least not in the species mentioned. Subsequently two guinea-pigs, whose vitality had been lowered by keeping them for a period of about a month in a dark place which was poorly ventilated, were injected with approximately the same amount of a pure culture as was used in the other animals. On the third day after the inoculation the animals began to show signs of illness, the rectal temperature being increased by about 2° F. One of the animals died on the eighth, the other on the tenth, day after inoculation. Post-mortem examination showed a pronounced nephritis in both animals. The cortex of the kidneys on removal of the capsule showed numerous minute hemorrhages; on cutting through the kidney the substance seemed softer and more friable than is normally the case. The pyramids were of a dark-red color, the entire organ appearing congested and œdematous. Culture tubes were inoculated from the kidneys, and a pure growth of the organism described by me was obtained.

The other organs of the animals showed no macroscopical changes. As Behla had shown that swine were apparently susceptible, a number of these animals were inoculated with cultures derived from the scales of a virulent case of scarlatina.

Animal No. 1: Weighing about twenty pounds, in good condition, skin perfectly normal; rectal temperature 101½ F. About 1 c.c. of a culture of the diplococcus was mixed with about 3 c.c. of distilled water and injected into one of the veins of the ear. During the first four days the animal showed no signs of any disturbance. On the fifth day the animal became restless and the rectal temperature rose to 103° F. On the seventh day a pronounced reddening of the skin was noticed, most marked on the abdomen; this lasted about thirty-six hours. On the tenth day the animal began to scale, the scales being most numerous on its abdomen and ears. Cultures made from the blood and scales showed the same organism as was injected. This animal was killed, and on examining its organs the kidneys were found to present a similar condition as was noticed in the kidneys of the guinea-pigs, with the exception that the right kidney showed a small abscess in the cortex. Cultures made from the kidneys again showed the same germ.

Animals Nos. 2, 3, and 4, weighing twelve, sixteen, and nineteen pounds respectively, were inoculated in a similar manner, with similar results in regard to the rash and scaling, the same germ being found in their blood and scales. In the third animal injected the eruption was more of a papular character and the reddening was not so marked.

Animal No. 5, weighing about twenty-five pounds, was injected subcutaneously in the abdominal region, the culture used being the fifth generation of the one used in the previous experiments. There was no reaction, except a rise in temperature of about two degrees on the fourth day after the injection was noticed.

I wish to state that the cultures used in these animal experiments were not isolated by means of "Platten giessen," but I am quite certain that they were not contaminated by other germs, as repeated careful examinations showed. The reason why I did not isolate the germs by means of the process mentioned was on account of the fact that their vitality is easily destroyed by heating, the cultures obtained by isolating

the germ by means of the plate method growing very poorly.

The conclusion that the germ described is probably the causative factor of scarlet fever was arrived at through what I think can be called fairly careful work. Most of the cultures mentioned in this paper were examined every day during the time of their growth, making about four thousand examinations *in toto*. In the majority of the throat and scale cultures the different germs were isolated as far as possible. One point which made the work very difficult was the large variety of organisms which are present in every throat and skin culture, and some of which very closely resemble the organism described by me when seen under the microscope, but which present a different appearance on cultivation. I would like to impress this fact on the minds of those who may wish to make experiments along this line, because otherwise it might occur that the investigator will throw up his hands in disgust when the scales of the first case of dandruff or eczema examined show a germ resembling the diplococcus described. Respecting the blood cultures the objection may be raised that the presence of the organism is accidental, but if the investigator will make control experiments it will be seen that this is not the case; furthermore, the ordinary micro-organisms present on the skin and in the air when dropped accidentally in a culture tube will grow readily in a few days; this germ grows as a rule exceedingly poorly in the presence of scarlatinal blood.

Another point to which I wish to call attention is the change in form which the organism undergoes, and which may lead to mistakes. A few words in regard to the streptococcus in scarlet fever. Streptococci were found in about thirty per cent. of the throat cultures. As a rule they were found in those cultures which were taken late in the disease and when there was a severe angina. In those cultures taken early on the first or second day of the disease they were seldom found. If they are the causative factor of scarlatina, and the throat is the gateway by which they enter the system, it stands to reason that they should be found early. In the blood streptococci were not found in a single instance. In the cultures made from the scales they were occasionally found, but not oftener than in the cultures made from the scales of healthy individuals.

Before concluding I would like to mention briefly a few differential points between the diplococcus scarlatinæ and similar organisms that have been found in the skin and naso-pharynx:

Micrococcus tetragenus subflavus: Flat, dirty-white colonies with shining surface; turns brown at the margins after three or four days.

Micrococcus tetragenus versatilis of Sternberg: Colonies pale yellow, which later become orange colored; grows profusely on ordinary media; is usually present in skin cultures.

Diplococcus coryzæ: Grows readily upon gelatin plates; forms white, glass-like, slightly elevated colonies.

Diplococcus albicans tardus: Much smaller; grows much more slowly; dark yellow growth on gelatin.

Micrococcus cumulatus tenuis: Found in nasal mucus; large single cocci associated in masses; colonies are oval and perfectly transparent.

Micrococcus albus liquefaciens: Liquefies gelatin readily; perfectly white, shining layer on agar-agar.

Diplococcus fluorescens fœtidus: Found in posterior nares; quick growth; brownish-gray layer; liquefies gelatin readily.

Micrococcus of Demme: Found in pustules of pemphigus acutus; colonies milk-white in color, never transparent.

Diplococcus albicans amplus: Not transparent, grow readily on gelatin.

Diplococcus luteus: Motile, yellow layer, later brown.

Micrococcus aerogenes: On agar yellowish-white colony.

Micrococcus agilis: Motile and possesses flagella

Micrococcus candicans: Milk-white colonies.

Micrococcus candidus: Snow-white colonies.

## A PRELIMINARY REPORT UPON THE USE OF PURE CARBOLIC ACID IN THE TREATMENT OF MASTOID WOUNDS AND CHRONIC SUPPURATION OF THE MIDDLE EAR.[1]

By WENDELL C. PHILLIPS, M.D.,

NEW YORK.

At a meeting of the Medical Society of the County of New York held February 27, 1899, Dr. Seneca D. Powell read a paper entitled "Carbolic Acid in Surgery," an abstract of which appears in the Medical Record of March 11, 1899. He said that the paper represented the results of his observations at his clinic in the Post-Graduate Medical School during the past fifteen years. About five years ago he had ascertained that in ninety-five-per-cent. alcohol he had an antidote to carbolic acid. He demonstrated before the society that a ninety-five-per-cent. solution of the crystals of carbolic acid could be rubbed freely on the hands and allowed to remain for a few seconds without any unpleasant effect from it, if the hands were then rinsed with alcohol. He said he knew of three cases of carbolic-acid poisoning in which alcohol had been successfully used internally. Many of the results to be described had been obtained by using carbolic-acid solution of the strength of one-half drachm to the ounce. In mammary, tuberculous, and other abscesses, granting that there is suppuration resulting from microbic action, our treatment to be effective must be capable of destroying these microbes. In these abscesses no difficulty need be experienced in controlling the suppuration if carbolic acid was properly used. The cavity must be thoroughly cleaned out by irrigation, followed by curetting; after this has been done the cavity should first be filled with strong carbolic acid and the acid evacuated, then filled with alcohol and the alcohol evacuated, and finally the cavity should be washed out with water. By this method he frequently succeeded in converting a foul pus cavity into a clean granulating wound in from twenty-four to forty-eight hours. Tuberculous abscesses should be swabbed out every day until healthy granulations were obtained. It was a mistake to suppose that ulcers and wounds would not granulate under such treatment. Bone abscesses were also amenable to its treatment.

Dr. D. B. St. John Roosa had used this treatment for two years past in mastoid abscesses, and had spoken highly of it. He had used it in cellulitis of the hand, lymphangitis, and empyema. He had recently evacuated two quarts of pus from a case of empyema, and had filled the cavity with a solution of carbolic acid of the strength of one-half drachm to the ounce. A piece of gauze had then been inserted into the opening, and the dressing had not been changed for a week or more. By this time there was practically no further discharge. He had used it in cystitis and erysipelas.

In the discussion following, Dr. A. M. Phelps said that he had verified in his own practice almost every claim made by the reader of the paper. In washing out tuberculous joints with carbolic acid there resulted a great deal of exudation, but the cases invariably

[1] Read at the fifth annual meeting of the American Laryngological, Rhinological, and Otological Society, Cincinnati, Ohio, June 2 and 3, 1899.

went on to convalescence, except when there was bone disease beyond the reach of the acid.

Dr. Powell also said that he had found carbolic-acid solution most useful in treating ivy poisoning, and had used it in many cases of injuries to the fingers, yet he had never seen any necrosis which seemed to be fairly attributable to its use.

Following the line of thought outlined in Dr. Powell's paper, I have for the past three months made use of pure carbolic acid in the treatment of mastoid wounds, chronic suppurative otitis media in which necrosis existed, and in the sinuses so often found in mastoid wounds, which are so difficult to heal. This treatment has proven very helpful.

I have prepared the carbolic acid by adding simply enough water to the crystals to hold them in solution; and at first the applications were all made by means of the cotton probe. Later on it was found that especially in the attic cases it was difficult to get the carbolic acid into contact with the tissues. In order to overcome this difficulty I had a spray apparatus made, with the tube so finely drawn that I was able to introduce it into the aural canal and spray the acid into the attic and middle ear. This method has been found to be very useful and effective. In nearly all the cases in which this method of treatment has been adopted the suppurative process has almost immediately commenced to subside.

Time will not be taken to give many detailed histories of cases, and it is understood from the title of this paper that it is to be but a preliminary report, and it is given to the members of this association that they may also, if they feel inclined, adopt this method of treatment and test it for themselves. That it has a helpful effect in necrosed conditions of the bone there can be no doubt. In several of my cases which had resisted all methods of treatment rapid healing followed its use. While others, and especially the middle-ear suppurations, are not fully cured, yet the improvement has been so marked that the patients have expressed themselves as heartily pleased with its use. It causes pain and discomfort for a few minutes, but the alcohol is more painful than the carbolic acid. It is advisable, if possible, to avoid using an excess of carbolic acid, thus obviating the necessity for using too much alcohol. Up to this time I have observed no ill effects, no inflammatory reaction, and no extension of the disease resulting from its use. In one case of probable tuberculous mastoid its effect was not sufficient to obviate the necessity for another curettage, but following the curettage its use has seemed rapidly to lessen the tendency to suppuration.

The histories of the following cases are briefly given:

Case I.—W. R——, aged forty-five years; mastoid operation, September, 1898. January 1st: The mastoid wound had closed in to a suppurating sinus extending into the mastoid antrum. No treatment had been of any value. January 7th: Began applications of pure carbolic acid every other day. The sinus entirely healed in seventeen days.

Case II.—M. F——, age forty-two years. On January 1st he had a suppurating sinus leading into the mastoid antrum resulting from a mastoid operation done November 11th. Up to this time the sinus had resisted all treatment and remained open. Began pure carbolic-acid applications on January 12th, and the sinus closed in fourteen days.

Case III.—J. H——, aged twenty-eight years; suppurating sinus from a mastoid operation performed in August, 1898. Began the pure carbolic-acid applications on January 10, 1899. The sinus closed in twelve days.

Case IV.—August 4th, M. B——, aged twenty-one years; otitis media suppurativa chronica with mastoiditis operation on January 28th. The tympanic cavity and mastoid cells were filled with pus which had perforated from a large sub-parietal abscess. All diseased bone and granulation tissue were cut and curetted away, leaving a large mastoid wound which was kept absolutely free from infection of pus from the tympanic cavity by daily applications of pure carbolic acid. The discharge from the tympanic cavity was profuse and resisted treatment. The use of pure carbolic acid was begun through the external auditory canal in February 20th, by means of a cotton carrier, and continued until about March 20th, when the spray of pure carbolic into the middle ear through the external auditory canal was begun. The patient was discharged May 1st with the mastoid wound entirely healed and the middle ear dry.

Case V.—A. R——, aged five years, had a mastoid operation on September 21, 1898. This patient was ill-nourished and tuberculous, and the mastoid wound persistently refused to heal. On November 3, 1898, another curettage was resorted to, which for a time improved the condition. Subsequently the whole wound developed a mass of suppurating necrosis. I began the use of pure carbolic acid on January 1st in the mastoid wound and in the middle ear. This was followed by marked reduction in the suppuration from the middle ear, and the mastoid wound improved, but there was a large surface of denuded bone, and the third curettage was done. After this curettage the carbolic acid was sprayed into the ear every second day and the wound packed with sterile gauze. The patient was allowed to go home on May 14th, with the wound almost healed, and the middle ear practically dry; on May 25th he was returned to the hospital with a profuse discharge from the middle ear due largely to negligence on the part of his caretakers at home.[1]

Case VI.—J. O——, aged two years, had a mastoid operation January 23, 1898. At this operation the mass of bone removed was very great and the tympanum was curetted. Under daily applications of pure carbolic acid the mastoid wound was kept clean and dry, but the middle-ear discharge remained profuse until the carbolic acid was used by means of an atomizer, when it began at once to improve; but as the middle ear was again filled with polypi the patient was again submitted to operation on March 18th. The entire wound was thoroughly curetted and the same treatment continued. The patient was discharged May 1st with the wound healed and the ear dry.

A number of other patients had at different times during the healing of their wounds spots of infection in various places, which were usually immediately rendered aseptic by one or two applications of carbolic acid, and the filling of the cavities with healthy granulations was not interfered with. In those cases in which the wounds show no tendency to granulation, and the depressions are found filled with pus, pure carbolic acid applied every other day causes small healthy granulations to spring up and greatly facilitates the final healing of the wounds.

I am indebted to Dr. H. H. Martin, hospital surgeon of the Manhattan Eye and Ear Hospital, for arranging these few histories which have been submitted.

**Typhoid Bacillus** persisting in the bladder possibly for three years appears less remarkable when we recall the cases in which abscesses containing typhoid bacilli have been observed six or seven years after the occurrence of typhoid fever in the patient.—Thomas Houston.

[1] August 1st: For one month the wound has been entirely healed, and will, no doubt, remain so.

## AN INTERNATIONAL LANGUAGE FOR SCIENTIFIC MEN—IS IT A POSSIBILITY?

By R. ELLIS, A.B., M.D.,
UTICA, N. Y.

In view of the fact that another international meeting will soon be held, it is time to bring up again the subject of an international language for scientific men, especially since there seems to be a scattered few who believe an international scientific language is a possibility, which is destined to pass through the stages of development into a reality.

Those who have attended international meetings, and have listened to the reading of papers with an absolutely zero comprehension, have felt the necessity for some common language, especially when some beacon light in the medical world has appeared and disappeared, with as much satisfaction to the listener as is derived from gazing at some great work of art, boxed and ready for shipment. Surely there is as much artistic satisfaction to be derived from gazing at this "packing," as in gazing at the clothes and the face of a living master of medical art, "reading his paper."

We must see the work of art to appreciate it; we must understandingly "see" the great men of the congress, else, so far as "papers" are concerned, we return home with a mere memory of a mixed-up mess of clothes, shape, and features—an experience as satisfactory as an American physician derives from his first lectures in Berlin, an experience which enables him to remember everything about the man, nothing about what he said.

We all agree that a common language should be spoken if the greatest benefits are to be derived; so at once comes the question: What language?

We have eight languages to select from: English, German, French, Spanish, Italian, Russian, Latin, and Greek. For several reasons we believe English to be the best language, but the foreign members of the congress would not agree with us—in fact, the members of this international congress would never agree upon a language of any leading race attending the meeting, so at once English, French, German, Italian, and Spanish are not to be considered.

Why not select three languages: English, French, and German? Because this would at once shut out other races, and confine the meeting to physicians of these three tongues—a result by no means to be desired, when one considers that an international meeting invites the world to send her beacon lights in medicine—yes, of a truth, the world, including not only England, France, Germany, Russia, and America, but Italy, Spain, South America, Japan, Holland, Belgium, Norway, Sweden, Denmark, and the very isles of the sea.

As the congress must be strictly international, we are compelled to select a language agreeable to all. That language must be either Latin or Greek. As modern Greek is a majestic and beautiful language, completely dressed with an up-to-date medical vocabulary, and superior in many ways to Latin, we are safe in saying Greek would be the choice of any congress. Now we have the international language—presto, what a change! from a distressing mixture of English, French, German, and at times Russian, Italian, and Spanish, we sink down into seats made as restful as downy pillows by delicious mental ease, as we digest in Greek words the contents of as many papers as we will to enjoy—papers by Germany's greatest pathologist, America's greatest surgeon, Italy's noted diagnostician, Russia's famed histologist, and England's great sanitary expert. No longer are we obliged to look wise as our brains are bewildered by unintelligible tongues; no longer will a German savant drag us through the labyrinth of his long words, so rapidly read as to bewilder even his best friend; no longer will a nerve and "nervous" specialist bring us into a condition of neurasthenia as he smoothly glides around, about, and in and out, gracefully explaining his discoveries concerning the neuron to listeners who look wise but understand nothing. "Enough, no more of that!" say our international-language enthusiasts; "every paper will be a Greek feast—a linguistic symposium understood by all, appreciated by all, digested by all."

Ye gods of Greece and Rome, what a feast! What linguistic luxury and revelry! The better to enjoy this feast, the "international devotees" would "brush up" between meetings by reading the necessary Greek journal, and by adopting Greek as the language of all society meetings—in fact, the whole matter could be settled if each county society would pass a resolution like this:

"*Resolved*, That from this date Greek shall be the language of all county meetings."

Such a resolution, added to the Greek medical journal, would exert a wonderful stimulus to the study of Greek, and in a comparatively short time the language would be understood by all progressive physicians and then by all men of science, for they would realize the advantages of a common scientific language.

Thus do our enthusiasts reason. Great Cæsar's ghost!—yes, and shade of the great Hippocrates too! Is it possible that any sane man believes we can adopt Greek as the universal language of science? Why, the man of science is so full of his own special work, and so shut in by the narrow fence about his daily life's work, that he could not possibly acquire and keep Greek, or any other language, as a working language.

I grant you that a few physicians have mastered German, or French, or Italian, so that they read well and understand fairly well, but among hundreds of progressive scientific men, I venture to state you will not find one "Yankee" that can understand perfectly a lecture such as one hears in the hospitals of Berlin or of Vienna; unless he has had very unusual opportunities to learn German. I know many can almost understand, but to appreciate a lecture not an important word should be lost, else much will be misunderstood or entirely lost. How much faithful study is required to understand a "heavy" paper, even in our mother tongue? Only last night I heard a lecturer state that "economic reform is likely to come through the agency of the Bible," a statement that puzzled me through the lecture until a friend cleared up the mystery by changing "Bible" into "buyer." The misunderstanding, or the not understanding, every important word in a lecture spoils the lecture as a whole, and destroys concentration of attention. If it is difficult to follow a lecture in the mother tongue, how much more difficult to follow a lecture in a foreign tongue, especially if delivered like "greased lightning"—a term that comes to me after listening to several "beacon lights" in Berlin.

Greek the language of science! Does any one know what it means to master a language? Yes, of a truth, those who have diligently studied and almost acquired a language will readily confess the persistent application required—an application that must be continued faithfully, else the dust gathers so thick that the words refuse to come readily from the mental machine, and a horrible linguistic twisting—a squirming squeaking—is the result of one's best efforts to speak.

There are many who speak simple French or German fairly well, but this requires a little grammar and a vocabulary of a few hundred words, which are

kept in the brain by constant reading and speaking; but who among this class can understand a lecture rapidly delivered in French or German?

But Greek!—*πρὸς τῶν θεῶν!* I have been a teacher of Greek for years, but I cannot speak Greek. Why? Because I have no opportunities to speak Greek, so I have placed no Greek words in the cerebral storehouse to gather dust and uselessly to fill up valuable space—in other words, I have stored up no Greek words because I cannot use them. If I could attend a scientific meeting occasionally, where only Greek would be heard, would it pay me to try to fill the storehouse with Greek words? Great shade of Æsculapius!—no! for between meetings the words would escape, and I should go to the county meeting with a very empty storehouse of Greek words, to be entertained by some linguistic freak, who had mastered Greek, but not the subject of his lecture. The very man whose words would be weighted with practical experience, and whose advice would be as refreshing as mellowed wine, would sit silently by, because he could not dress his full, rich experience in the language which his companion uses to dress a shadow.

So in our international meetings, the very men who should be heard would silently listen to lean papers dressed in fine Greek words by men whose only ability might be in their power to say little in much Greek. The result of this would be that only those knowing Greek would attend the meetings, and the congress would develop into a "Greek medical society." Sad it is that there is not only no royal road to the mastering of a language, but almost no road at all; sad it is that this narrow path is so rough and difficult that thousands fall by the wayside after covering a very little ground. The thousands of students who "expect to learn German" and never do, are a strong proof of the difficulties along this narrow path.

Many find little difficulty in learning to read a language, because the words are already "in storage" in books and lexicons, ready for the eye to see and the brain to recognize; but when, in order to speak a language, the student tries to transfer these words from books into his own cerebral storehouse, ready to be used by his tongue at a second's notice—ah, there's the rub! that's the "pons asinorum" over which so few cross, especially when the discouraged ones see the long pons grammaticæ ahead with its never-ending rules and exceptions.

The brain centres for word memory and word formation are forced to acquire a new language only after persistent study and endless repetition. The intelligent child requires fifteen years to know its mother tongue, while the intelligent man, in his busy sphere of life, requires his spare time for at least five years, to half master a new language.

Of course an embryonic physician could easily learn Greek by living in Athens for two years, but the stern struggle of competitive general practice would soon "knock out" most of this Greek, unless his surroundings gave him constant opportunities to converse in medical Greek, which differs almost as much from Greek as medical German differs from German. I once knew an illiterate physician, who attended mass in a little town, where his fellow-worshippers looked up to him with great respect, because "he understands Latin—all doctors have to." The doctor looked down upon them from his intellectual height with enraptured face, as he drank in the Latin of the mass. Poor old fellow! He did derive so much comfort from his "Latin," even though he knew he did not understand a word of it. Were Greek to be the language of science, many a physician would listen with attentive face to the reading of papers (even though his brain understood nothing), and return home from the congress, sincerely believing himself well repaid for his journey; but the man of true progress is not to be deceived in this way. He would feel compelled to join another international congress where Greek was not the chosen language.

Of a truth, the ability to keep in the cerebral storehouse a little French, German, and possibly Greek, requires so much hard work that most brains grow weary and quietly drop the load. Of course the ability to acquire and retain Greek is possessed by many, but very few indeed, stimulated by the international meeting, would keep up their imperfectly acquired language for the sake of the next meeting. Such a struggle is contrary to cerebral tastes. The mind necessarily objects to a mixture of hard practice and dry Greek—they do not mix well and they will not.

The value of an international meeting, however, is not in hearing papers read. These are best digested by selected reading in the privacy of one's study, especially since empty papers are often presented by weak men, who have not earned the right to present a paper—men like Dr. Bastbom, who is sure to be in the front seat at every meeting, and sure to have something to say, which, when added to his "embonpoint," is really of considerable weight.

Again, a "heavy" paper requires careful reading rather than attentive listening; so the papers of most enduring influence are not those listened to by most, but those read by most. But the true value of an international meeting lies not in the papers read, but in the peculiarly stimulating environment of a great congress of medical men—on the outside, and not in the inside of the congress. The rubbing against new men, new ideas, new hospitals, new surroundings, new people, scrapes off the rust, while the polishing is acquired by the stimulus derived from great men, with their great deeds, and their still greater thoughts and plans.

What a stimulating influence comes from these beacon lights! My memory of one meeting is now a confused mass of impressions, out of which shines one man—Virchow, with his fatherly blessing. Of a truth the beacon lights of a congress illuminate its entire environment, not so much by their papers, as by their presence in places where their influence can be personally felt. Surely the influence of a score of such lights upon an ambitious physician must be almost as great as the influence of the famous "Saturday Night Club" upon a humble literary plodder, invited to be a table companion of Emerson, Holmes, Thoreau, and Longfellow. The "uplifting" would come, not from what these literary giants might say, but from the elevating atmosphere inevitably associated with a group of brilliant men—an atmosphere that stimulates devotion, and lessens the "Sturm und Drang."

So with international medical meetings: what may be said is not of great value, except that part of it which may be thoughtfully read, but the atmosphere surrounding such a gathering elevates and ennobles an attendant as he realizes the dignity and grandeur of the "profession universal," especially when at such gatherings we touch elbows with the medical geniuses of the day, and see that the vast medical army of America, England, France, Germany, Russia, Italy, Spain, Holland, Belgium, and Japan is marching shoulder to shoulder, each daily knowing what the other is accomplishing, and each striving to keep in the front rank of progress and discovery.

Those who returned from the congress in Moscow brought back, not reports of papers read, but glowing accounts of medical and surgical progress, accounts gained from personally seeing the brilliant medical men of Russia, at work in "the best laboratories and hospitals in the world"; glowing accounts gained not

from "papers," but from the stimulating atmosphere of the congress, especially the fine "social atmosphere" surrounding the ever-zealous Russian, while scores brought back with them a few papers, to be digested by study, realizing and confessing that, after all, few of the papers were of great value, while the "atmosphere" of the congress was of tremendous value.

From experienced men whose opinion is of value, we know a physician should not go to an international meeting to hear papers read, any more than a United States senator goes to Washington to hear the speeches in the senate—of course not—he attends the great congress because he knows he will be a part in all that goes to make up that congress; so, wise senator that he is, he reads the important speeches, and lives absorbed in the senatorial atmosphere. When anything of importance is to be presented, you will always find him in his place; when that matter is settled, you will find him "drifting."

So we are not to enjoy the luxury of an international language, but we are to go on "in the same old way," each attendant doing his best to churn out of the meeting all the cream he can—a churning that always gives rich cream to some, skim-milk to others. To-day men of great reputation in the medical world are honored by hearers as well as by readers. Men of lesser reputation may have many readers; they must expect to have few listeners, especially since there are so many "big" papers and so many "big" men, and the brain grows very weary of listening to many long papers, unless back of these papers is the striking personality of a medical genius. The time will come when, by some fair arrangement, a translation of every paper presented to the international meeting can be secured for a small price by those who realize the importance of selected "paper study" rather than general "paper listening."

In conclusion, an attendant at an international medical congress should meet the "beacon lights" as well as hear them; he should examine carefully the interesting and important "field" of the congress; he should go everywhere and see everything; he should postpone the reading of his selected papers until he returns to the privacy of his study at home.

## Clinical Department.

### MULTIPLE SINUS DISEASE FOLLOWING INFLUENZA.[1]

By CHARLES STEDMAN BULL, M.D.,

NEW YORK.

This case is of interest because of the extent to which the deep sinuses of the face were involved and because of its rarity.

The patient was a lady, aged fifty-eight years, who had had a sharp attack of grippe, with high fever, but without pulmonary or abdominal complications. At the end of the second week, during which there had been a profuse discharge from the nose, she began to complain of a constant dull pain in the right cheek, just beneath the malar prominence. It was thought by her physician to be a decayed molar in the upper jaw, and was treated by anodynes and applications to the gum; but when conjunctival chemosis appeared, she was advised to consult an oculist and came to me. After examination I concluded that she had an abscess of the antrum, and there were several decayed teeth in the right upper jaw. I opened the antrum through the canine fossa and evacuated about two drachms of fetid pus. I enlarged the ostium maxillare in the nose, and then syringed through and cleaned out the antrum with the curette. A drainage tube was introduced into the antrum through the nose, and the antrum was irrigated twice daily. At the time of the operation the nose was also thoroughly cleansed and examined, but nothing suspicious was found. Four days later pus began to drop from the nose, and another examination of the middle and superior nasal meatus proved that empyema of the ethmoid was present. As all signs of orbital complications were absent, I decided to enter the ethmoid through the nose, which was immediately done in the usual way, the natural opening being enlarged, and the cavity of the ethmoid was thoroughly curetted. After the cavity was washed clean the bony wall between the ethmoid and the sphenoid antrum was found partially absorbed, and pus exuded from the sphenoid antrum. This cavity was also curetted and all the contents were removed, and it was then freely irrigated through the nose. The patient made a prompt recovery; the discharge grew rapidly less in quantity and thinner in quality, and the temperature subsided to the normal. She, however, complained of constant dull frontal headache, which at times was quite severe over the eyes, and the ocular conjunctiva remained more or less congested. At times there was also a slight rise in temperature. The persistence of these symptoms convinced me that the frontal sinuses were involved, and the patient was told that another operation was necessary, to which she consented. A vertical incision was made through the skin of the forehead, extending to the root of the nose, and this was joined by a horizontal incision, about two inches and a half long, just beneath the line of the eyebrows. The two triangular flaps of skin were turned up, and an opening was made in the bone with a trephine in the median line. The septum between the frontal sinuses was found broken down, and the sinuses were full of pus. Small fragments of bone from the septum were removed, and then both the cavities were thoroughly curetted and carefully washed out. The infundibulum was enlarged and free irrigation was carried out through the nose. The flaps of skin were brought together with deep sutures, and the usual antiseptic dressings applied. The wound healed promptly, the headache disappeared, and the discharge from the nose ceased on the third day. At the end of two weeks, after a very careful examination of the nose and pharynx, the patient was discharged and went to her home. She remained well for about two weeks, and then complained one morning of pain in the right ear, which rapidly became very severe, and was accompanied by a rise in temperature and swelling, redness, and tenderness over the mastoid region. The pain was severe all night, but was relieved in the early morning by rupture of the membrana tympani and the discharge of blood and pus. A surgeon was called that morning, recognized disease of the mastoid, and operated at once. The antrum was found full of pus and the bone was somewhat diseased. The patient recovered rapidly from this operation and remained in good health for nearly two months. During the inclement March weather, however, she contracted pneumonia and died on the sixth day, apparently from heart-failure.

One of the interesting features in the case was the relatively long time which elapsed between the date of operation on the frontal sinuses and the development of the aural complication. There is no doubt in my own mind that the starting-point of the very extensive sinus disease was the rhinitis caused by the grippe, and that the empyema began in the ethmoid and involved the other sinuses secondarily. The operation on the mastoid showed such extensive bone disease that it must have preceded and caused the attack of

[1] Read before the Practitioners' Society, May 12, 1899.

acute otitis media, which is rather reversing the usual process, for we cannot imagine a suppurative otitis lasting long enough to produce abscess in the mastoid antrum without causing more pain and a perforation of the drum-head early in its course.

## REPORT OF A CASE OF CEREBRAL MENINGITIS, MANIFESTING EXTRAORDINARY HIGH TEMPERATURE.[1]

By R. B. CHRISTIAN, M.D.,

LITTLE ROCK, ARK.

Lura Williams, aged twenty-six years, a pupil at the Arkansas School for the Blind, was a large, fat, well-developed woman. Her menstrual functions had been irregular for some time and had been suppressed for about six weeks prior to the beginning of her last illness. With this exception her health had been fairly good. On April 16, 1899, she felt ill and complained of fulness in the head and some nausea. Upon examination at 8 P.M. she was found to have a fever of 105° F., and at 9 P.M., when I visited her, the temperature was 104° F.

And now begins a record of remarkably high temperature, which was carefully and frequently observed, and verified by the use of five thermometers, three of which were broken, when the excessive heat would have forced the column of mercury higher than the capacity of the instrument would allow.

April 17th: 8:30 A.M., mouth 110° F. (thermometer broke); 9 A.M., mouth 108°; 12:30 P.M., mouth 98.5°; 4 P.M., mouth 108°; 9 P.M., mouth 110°.

April 18th: No record (omitted or lost).

April 19th: 10 P.M., mouth 110°.

April 20th: 2 A.M., mouth 102°; 8 A.M., mouth 114°; 11 A.M., mouth 114°, axilla 110°; 1 P.M., mouth 110°, axilla 110°; 3:30 P.M., mouth 114°, axilla 114°; 7 P.M., mouth 109.4°, axilla 114°; 10 P.M., mouth 112°, axilla 106.4°.

April 21st: 8 A.M., mouth 114°, axilla 109.4°; 11 A.M., mouth 114°, axilla 114°; 4 P.M., mouth 113°, axilla 111°; 10 P.M., mouth 109°, axilla 114°.

April 22d: 8 A.M., mouth 114, axilla 114° (thermometer broke); 12 M., axilla 105.4°, pressing pain in the head: 3 P.M., axilla 114°; 6 P.M., axilla 101.8°; 9 P.M., axilla 109.2°; 9:30 P.M., without pain and rational.

April 23d: 1:30 A.M., temperature normal; 7 A.M., mouth 99°, axilla 99°; 9 A.M., mouth 98.5°, axilla 98.5°; 12 M., mouth 114°, axilla 102°; 3 P.M., axilla 105°; 7 P.M., mouth 110°, axilla 114°.

April 24th: 1 A.M., mouth 114°, axilla 114°; 6 A.M., mouth 98.5°, axilla 98.5°; 8:30 A.M., mouth 114°, axilla 114° (very sleepy); 12 M., mouth 98.5°, axilla 101°; 4 P.M., mouth 114°, axilla 114°; 9 P.M., mouth 105.6°, axilla 108°.

April 25th: 2 A.M., mouth 98.5°, axilla 98.5°; 6 A.M., mouth 98.5°; axilla 98.5°; 8:30 A.M., mouth 111.75°, axilla 116°; 11:30 A.M., mouth 116°, axilla 116°; 4 P.M., axilla 108°, severe pain in head; 6 P.M., mouth 117°, axilla 112.6°; 9:30 P.M., mouth 117°, axilla 117°.

April 26th: 3 A.M., mouth 100°, axilla normal; 6 A.M., mouth 105°, axilla 104.4°; 8:30 A.M., mouth 114.8°, axilla 101.2°; 11 A.M., mouth 118, axilla 118°; 4 P.M., mouth 108°, axilla 105.4°; 7 P.M., mouth 112°, axilla 118°; 10 P.M., mouth 108°, axilla 105°.

April 27th: 3 A.M., mouth 100, axilla 100°; 7 A.M., mouth 118°, axilla 118°, very severe pain in head, pulse 110; 11 A.M., mouth 102°, axilla 103.6°, pain relieved and menses appeared; 4:30 P.M., mouth 101.4°, axilla 101.4°; 9:30 P.M., mouth 111.4°, axilla 117°.

April 28th: 2 A.M., mouth 118°, axilla 118°; 7 A.M., mouth 105°, axilla 107°, 8:30 A.M., axilla 108 (thermometer broke), pulse 116; 4 P.M., mouth 102°, axilla 102.6°; 10 P.M., axilla 101.4° (patient unconscious).

From this date on the temperature ranged from 99° to 103°, until May 9th at 11 A.M., when it rose to 103.4°; at 3 P.M. 104.6°, and at 8:30 P.M. 107.2°. Death occurred at 12:40 on May 10th. For ten days prior to death the patient was in a state of deep stupor, and it will be observed that there was no extraordinary elevation of temperature after she got into this condition until a short time before the end came. The disease was without complications and was confined to the encephalon alone.

[1] Read before the Arkansas Medical Society, May 10, 1899.

## AN INTERESTING CASE OF MEMBRANOUS SORE THROAT.

By BEVERLEY ROBINSON, M.D.

NEW YORK.

A young lady, nearly eighteen years old, was attacked with what appeared to be during several days an ordinary case of follicular tonsillitis. At the expiration of this time, some patches of white membrane appeared between the tonsillar follicles, and the local and general condition of the patient was worse rather than better, viz.: there was increasing pallor, loss of strength, and marked swelling on both sides of the lower jaw, with increased obstruction of the fauces, due to infiltration of all the soft tissues. In addition, on March 3d, there was intense pain in both ears and in the back of the head. A culture was made from the exudation on the throat, March 4th, by Dr. William H. Park. On March 5th, in the morning, there was an attack of pronounced heart failure, which repeated itself several times during the day.

In the early morning of March 6th the patient was soporific, indifferent to surroundings, with the pulse and heart action weak, and increased pallor of face and continued swollen condition over the parotid region, without very marked enlargement or tenderness of the lymphatic ganglia. The patient was restless, turning from the back to the right side and again on the back, with the mouth agape all the while, and breathing stertorously, evidently from throat obstruction. I examined the throat at this time and found the membrane not only covering both tonsils to a great extent, but also covering in part the pillars of the fauces and uvula. I then injected into the left thigh, on the outer aspect, two thousand units of anti-diphtheritic serum, No. 8, of the health board. Within two hours the patient awakened easily, said she felt decidedly better, and drank a glass of milk with brandy through a glass tube.

About midday I examined the throat again and could discover no membrane on the uvula or fauces, and less on the tonsils than before the injection of serum. This was fifteen hours after the injection. Nine days later, March 15th, the patient had another attack of heart failure, and was restored only by repeated stimulation in different ways and notably by two hypodermics, one of digitalin, the other of atropine and a small quantity of morphine. Oxygen, mustard, hot-water bottles, brandy, strychnine, and strophanthus were also employed. In connection with this attack of heart failure there was a sudden and violent outburst of pain in the throat. In recovering from the attack the patient referred to a gone feeling, as it were, in the epigastric region. During many days there was a semi-paralytic condition of the soft palate, which was also accompanied with marked albuminuria. Although there was pronounced dysphagia, at no time was there regurgitation of liquids or solids through the nasal passages.

On March 15th the tonsils again became much swollen, but without recurrence of membrane. They took on a baggy, œdematous appearance. The throat was more obstructed, the swallowing painful and very difficult. Suddenly, during the day, there was a moderate loss of blood (about a teaspoonful), with mucus coming from a particular point of the right tonsil. There was no discharge of pus.

In the evening Drs. Janeway and Bull saw the patient. After examination of the throat, local interference was decided against. Pus was suspected but not discovered.

In view of the uncertain outcome of an incision into the tonsil, of the patient's general condition, and the fact of a general anæsthetic being required in case of operation, the latter was delayed.

The next day, after a very uncomfortable previous night, the patient's local condition was decidedly improved. From this time on convalescence progressed gradually. On March 26th, however, there was a faint attack on attempting to go up one flight of stairs, although assisted vigorously by a nurse. On March 27th, three weeks after the antitoxin injection, a small amount of pus came from the right tonsil, while the throat was being examined.

In the case reported the fever was very slight at most of the time, and the highest point reached by the thermometer under the tongue was 101° F., and that lasted only a few hours. There were certain symptoms pointing to grippe as possibly causative, viz.: intense pains in the lower limbs, ears, head, throat, and cheeks.

Prior to the first attack of heart failure, the patient had used different antiseptic sprays and gargles, and taken frequent doses of cubebs, rhatany, and milk and whiskey. The report of the board of health, after a culture was made, was that the case was not diphtheria, as no Loeffler bacillus was discovered. A controlling examination of another swabbing and culture, made by Dr. F. E. Sondern, was that only streptococcus and staphylococcu scould be found—no Loeffler. We must conclude, therefore, that we have here described a case of pseudo-diphtheria or membranous sore throat, follicular in the beginning and finally complicated with or changing to another somewhat distinct form of angina. The old teaching, the clinical one, says diphtheria. The new science gives us most of the clinical manifestations of toxæmic diphtheria, but labels the disease otherwise. Practically, the antitoxin of diphtheria saved the girl's life, I believe. My bias, hereafter, would be in any case of doubtful membranous sore throat, and particularly when the signs of poisoning are increasing and threatening, to inject antitoxin.

I would be glad to be informed to what extent the antitoxin is responsible, if at all, for the transient albuminuria. I would also suggest the question as to whether such cases as mine require the usual rules of room disinfection, applicable to true diphtheria, to be carried out. Are such cases contagious and how? As to true diphtheria I have my serious doubts whether it is carried in the air in many instances in which proper care and cleanliness prevail. What I do believe is that it is inoculated frequently from the membrane, or secretions, when carried even to a healthy mucous membrane. The atmosphere surrounding a diphtheria patient may, I believe, cause the Loeffler bacillus, already present in another, particularly a child, to breed or develop more abundantly and become toxic from being inoffensive. Foul air, notably that impregnated with sewer gas, will occasion the same result. Paralysis of the palate has long been known to follow occasionally membranous, erythematous, and other forms of angina. It is not necessarily pathognomonic of diphtheria.

At the expiration of the third week from the time the antitoxin was given, albumin disappeared from the urine. During the last ten days of its presence varied nutriment was allowed and even advised. Beef juice, eggs, bread, underdone beef, and mutton were eaten, and, as I believe, with evident advantage. Of course, milk was freely taken. The microscope was not used to search for casts, nor was it deemed altogether essential, although lack of time and perhaps negligence was the reason why this research was not made. An interesting query presents itself in this regard, as in many cases of moderate albuminuria which accompanies acute disease of a contagious or infectious type: How far should diet be restricted in its cure? In my own belief, when there is little or no fever, great pallor, and the patient is suffering from weakness and depressed nerve force, the true way to govern such cases successfully is to give food and plenty of it in small or moderate amounts, frequently repeated, and not to be too restrictive. The albuminuria disappears in due course just as other symptoms of acute toxæmia also disappear.

On March 27, 1899, I received a letter from Dr. William H. Park. In it he writes as follows: "I am afraid I did more harm than good in making the culture, for its negative results were altogether misleading." Not only were Dr. Park's results misleading, but also those of Dr. Sondern, reached later. How far then are we to be guided by mere bacteriological research when the clinical aspects of a case point clearly in a different direction? Again, how many cultures are required to determine definitely the nature of a membranous sore throat? These and still other inquiries are of the greatest practical importance. Only last winter I had a private case of angina labelled diphtheria by the board of health. I injected antitoxin in this case also, although the general and local signs were of mildest type. The patient was seen with me by Dr. Herman M. Biggs, who could confirm my statement. In this instance every possible care and attention were instituted during several weeks, much to the annoyance and discomfort of the household, to shield and protect other members of the family. This was done, of course, on the plea that, although very mild in form, it was a true case of diphtheria, and therefore capable of carrying the infection to others and possibly causing grave disease in individuals with different constitutional tendencies or local conditions. What I claim is this, that in all these instances there should be personal consultation with an authorized member of the health board and the family practitioner, so as to settle the proper basis of sanitary procedure before absolute rules of action are carried out. This statement is further borne out through the fact that already we know that the Loeffler bacillus may be present in certain throats and occasion no real disease, and again because the Loeffler bacillus may be mistaken at times, even after careful microscopical examination, for other relatively inoffensive forms of bacteria. Besides, are not streptoccocci and staphylococci, after all, carriers many times of more virulent noxa than the so-called diphtheria bacillus? Many closely observed clinical facts seem to demonstrate it.

In conclusion I would add that Dr. W. M. Tomkins, who was with my patient very constantly during the time of her severe illness, is of the opinion that the tonsillar hemorrhage was indicative of suppuration of the tonsil. I am not prepared to make this admission. I am sure that I have seen more or less blood exude from the tonsils of patients affected with diphtheria on several occasions. I fail to recall the case of a tonsillar abscess in diphtheria preceded a short time by a hemorrhage. I cannot believe that the pus which came from the right tonsil on March

27th had been concealed during twelve days and only at that date became manifest. On the contrary, I believe it formed rapidly during a few days previous to being seen, and developed insidiously without obvious symptoms.

## CEREBRO-SPINAL MENINGITIS WITH ULCERATIVE ENDOCARDITIS AND ABSCESS OF MYOCARDIUM, DUE TO THE DIPLOCOCCUS INTRACELLULARIS OF WEICHSELBAUM.

By L. NAPOLEON BOSTON, M.D.,

BACTERIOLOGIST TO PHILADELPHIA HOSPITAL; INSTRUCTOR IN OBSTETRICS AT MEDICO-CHIRURGICAL COLLEGE; PHYSICIAN TO OUT-PATIENT DEPARTMENT, HOWARD HOSPITAL, PHILADELPHIA.

It is through the courtesy of Dr. D. E. Hughes, physician-in-chief to the insane department of the Philadelphia Hospital, that I am privileged to present a report of this rare and interesting case.

C. C——, white, male, aged fifty-six years, a papermaker by occupation, was admitted to the Philadelphia Hospital, March 8, 1899, suffering from the result of a three weeks' debauch, complaining of nausea, anorexia, tenderness over the epigastrium and abdomen. His tongue was coated, the pulse was normal, the heart sounds were rather weak, and a systolic murmur was heard at the level of the aortic cartilage. The lungs showed general signs of bronchitis and at the borders on the right side were slightly œdematous.[1] Three days after admission the sputum was found to contain tubercle bacilli. At this time the patient showed great improvement and was apparently in condition to leave the hospital. The fact of his having no home was the reason for his remaining in the institution. On March 14th (six days after admission), he was noticed to be talkative during sleep, and an examination showed the presence of consolidation at the apex of the right lung. There was little or no change in his condition until the night of March 19th, when he developed marked delirium, which was soon followed by a semi-comatose state; the extremities were spastic and the reflexes increased; the eyes were tightly closed, except when an effort was made to arouse him; there was paralysis of the bladder and rectal sphincters. Temperature, 101° F. at 2:30 P.M.; 102° F. at 6 P.M. The following day there was marked rigidity of the muscles of the nucha, and a tremor of the left arm, hand, and foot, resembling that of paralysis agitans, was noted. March 21st there was general relaxation, except for a slight rigidity of the neck muscles; the eyes were turned to the right, which conditions remained until death, which took place at 3 A.M. Temperature, 8 A.M., 103° F.; 12 M., 103.4° F.; 6 P.M., 104° F.

The post-mortem examination revealed slight abdominal distention. There was adhesive pleurisy at the apices, more pronounced on the right side. The pericardium contained 10 c.c. of straw-colored fluid. There was a milk spot over the right ventricle; the heart muscle appeared rather flabby; all the orifices were of normal size; the aortic leaflets showed some sclerosis at the bases; there was also atheroma of the arch of the aorta. The mitral valves showed small areas of sclerosis along their free borders. The left auricle presented an erosion 5 mm. in diameter, which exuded a bloody pus when firm pressure was made. On incision there was found to be an abscess 1 cm. in diameter, extending well into the wall of the auricle, reaching the base of the mitral leaflets. The lungs showed tuberculosis at all stages; the cavities were few and very small. Cut sections from various portions of the right lung were found to sink when placed in water. The involvement of the left lung was apparently very recent. The spleen measured 12 x 9 x 2 cm.; the pulp was rather soft and of a dark chocolate color. The liver weight was 1,310 gm. A small amount of fatty change was noticed. In the bowels a few small ulcers, presenting the characteristics of tuberculous lesions of this organ, were found. The kidneys gave evidence of a mild grade of acute nephritis.

Brain: Everywhere the pia mater and arachnoid were infiltrated with an extensive exudate, 1 mm. in thickness over portions of the frontal region, lending to the organ a grayish-yellow color, through which many of the blood-vessels stood out prominently. The exudate was thickest over the frontal and parietal regions, while along the fissures it was found to be quite liquid. The spinal cord presented a similar condition throughout its entire meningeal envelope. The posterior portion appeared to show most involvement. On puncture of the lumbar region a rather large amount of fluid escaped.

Cultures made from the meninges of the brain and cord and from the endocardial abscess were as follows: Brain: bouillon two, glycerin agar three, serum two. Cord: bouillon two, glycerin agar two, serum two. Abscess: glycerin agar two. Four of these cultures showed no growth after being allowed to remain at a temperature of 37° C. for forty-eight hours, yet in every case a large amount of the exudate was carried on the inoculating needle. Characteristic colonies developed on both agar and serum, with the addition of one or more colonies of the staphylococcus pyogenes aureus in each tube. In every case the bouillon showed the characteristic clouding at the end of twenty-four hours. Cultures from the abscess of the heart showed only diplococci, which presented all the characteristics, both as to growth and staining, of the diplococcus intracellularis. Further study of this diplococcus, found in the meninges and in the abscess, showed nothing more than has been written by Councilman, Mallory, and Wright. Coverslip smears were made from the exudate of the meninges and from the pus of the abscess. Those from the meninges showed diplococci, most of which were situated in the pus cells and leucocytes, and gave up their stain when treated with Gram's solution. In most cases the number of cocci in a cell varied from two to ten. Few micrococci were seen apparently in the pus cells; and many more were found in the stroma around the cellular elements. Those from the abscess showed only diplococci, which were in every way identical with the organism found in the meninges.

Five minims of a twenty-four-hour bouillon culture were injected subcutaneously into the flank of a white mouse. The animal showed no apparent discomfort for six days, when it was noticed to be stupid, and died on the morning of the seventh day. At the site of puncture a small abscess, the size of a pea, the inner wall of which was formed by the peritoneum, and containing a thick greenish-yellow pus, was found. Otherwise the animal's body appeared normal. Cultures from this abscess developed only diplococci, which possessed all the characteristics of the diplococcus intracellularis. Coverslip smears were found to contain many diplococci, both within and outside the pus cells. But in every case the number of organisms in a cell was greatly lessened, while the number of cocci free from cells was markedly increased.

A guinea-pig was given, by means of injection into the mouth and nose, 5 to 25 ♏ of a twenty-four-hour bouillon culture, care being taken not to break the mucous membrane. This process was repeated daily for a week, but the animal showed no discomfort whatever and is yet perfectly healthy. Tissue for

[1] The history and daily ward notes were carefully taken by Dr. J. F. Murphy, resident physician.

sectioning was taken from the brain and cord by Dr. Kaltyre, assistant pathologist. It is to be regretted that the report on the same has not yet been received.

The relation existing between ulcerative endocarditis and meningitis has been pointed out by various authors. Strümpell and Dercum ("American Textbook of Nervous Diseases") regard meningitis as a complication of ulcerative endocarditis. The latter author suggests that fragments and organisms are carried from the endocardium to the meninges by the blood. Anders, writing of the complications of epidemic meningitis, states "that endocarditis may be noticed, though rarely." Councilman, Mallory, and Wright report a case in which foci of purulent infiltration into the myocardium, in connection with pericarditis, were present. "No diplococci were found in connection with these lesions."

The author has not attempted to collect all cases from the literature, yet, so far as his observations go, this appears to be the first case in which purulent cerebro-spinal meningitis has been accompanied by ulcerative endocarditis and abscess of the myocardium, the exciting cause being the diplococcus intracellularis meningitidis.

## Progress of Medical Science.

**Oxygen Tension and the Lungs.** — Paul Bert's famous dictum, that the effects on animals of barometric pressure was due to the tension of the oxygen in any given atmosphere, has been brought to the test by J. Lorraine Smith. In the *Journal of Physiology*, vol. xxiv., 1899, the results of a series of experiments on respiratory exchange under increased oxygen tension are recorded. He finds that his experiments fully confirm Bert's results. As a practical result of the author's studies the relations to caisson disease are referred to. He shows that if oxygen be taken into the lungs at a tension above that of the ordinary atmosphere, it acts as an irritant and can produce inflammation, and since workers in caissons are frequently subjected to a pressure of at least four to four and one-half atmospheres, there are dangers to the lungs which arise solely by reason of the oxygen in the atmosphere.

**Malaria of the Central Nervous System.**—Marinesco (*Comptes Rend. de la Soc. de Biol.*, 24, 3, 1899) reports an interesting case of malaria in which the autopsy revealed among other details a severe degree of nerve disease. The examination of the brain showed that the gray matter was completely discolored and almost violet in hue; the white matter also was of a mottled grayish blue. On microscopical examination it was discovered that this discoloration was due to an immense number of minute pigmented bodies which filled the arterioles and capillaries of the brain and cord. These small pigmented bodies were the Laveran malarial parasites, and their presence in such overwhelming numbers in the vascular system of the brain and cord must be considered a great rarity.

**Action of Diphtheria Poison on the Heart.**—Dr. F. Rolly, first assistant to the children's clinic at Heidelberg, as the result of a series of experiments on animals with the diphtheria toxin (*Archiv für experimentelle Pathologie u. Pharmakologie*, 42, 1899) concludes that—(1) The fall in blood pressure induced by the poison of diphtheria is due to paralysis of the vasomotor centre, and also to the paralysis of the heart, which in spite of artificial respiration soon ceases to beat. (2) This action on the heart is direct and in warm-blooded animals is independent of the nervous system. (3) The paralysis of the heart develops after a more or less definite latent period. Direct injection of the diphtherial poison or transfusion of lethal diphtherial blood interferes with the action of the isolated normal rabbit's heart only after a certain latent period. (4) On the other hand the action of the poison takes place at the same time, even if, before the appearance of poisonous symptoms or at the beginning of such toxic action, the heart is washed out with normal blood. (5) This property possessed by the diphtheria poison of action on the heart leads to the opinion that the poison gradually takes hold of the heart muscles and is seemingly stored up there until its complete action is manifest; this further explains the continuance of functional heart disturbances after many of the acute infections.

**Fulminating Paralysis.**—A case of so-called fulminating paralysis was observed by Brannt (*Allgem. Zeitschr. f. Psychiatrie*, Bd. 55, Heft 5) in a man aged forty years, who was alcoholic and of neuropathic antecedents. His previous health had been excellent, and syphilis could be excluded from the history. After prodromal symptoms extending over a period of a few weeks, delusions of grandeur, irrational actions, etc., epileptiform convulsions set in, which lasted almost six days, till death took place. The autopsy revealed the existence of a recent paralysis, and the cause of the convulsive and paralytic seizures, which were confined to the right side, was seen to be an atrophy of the left basal ganglia and œdematous infiltration of the corresponding hemisphere.

**On the Origin of Choked Disc, and a New Explanation of Its Causation.**—J. Deyl (*Wiener klinische Rundschau*, April 23d), as a result of a number of studies on optic atrophy, concludes that choked disc is due to a compression of the central vein of the retina at or before its entrance through the outer sheath of the optic nerve. This causes either a hydrops of the laminæ or irregular extravasation of blood, thus compressing the strands of the nerve in the pia. Through the induced tension of the dura the central nerve is locally compressed to a sufficient degree partially to hinder the blood current. The accumulation of fluid in the anterior part of the intralamellar space is evolved by an increase of intracranial tension, or it may be produced by an occlusion of the optic foramen. Under special individual anatomical conditions this occlusion may also be the result of hypophysis tumors or acromegaly, and in such cases the occasional occurrence of choked disc is explained by stasis of the lymph current and the attendant compression of the central vein. Since at varying distances from the posterior wall of the optic globe the central vein pierces the sublamellar space and dural sheath with a greater or less degree of obliqueness, corresponding to this distance varying degrees of intralamellar hydrops are necessary to produce compression of the vein. So long as the ampulla-like dilatation of the dural sheath does not reach the point of emergence of the central vein from the outer sheath, a choked disc cannot result in spite of the existing œdema. A removal of the tension producing the hydrops by a cure of the intracranial disease or by trepanning, allows the collapse of the distended sheath; the pressure on the vein ceases and the choked disc disappears. The author also calls attention to a hitherto unpublished symptom, viz., the absence of the artificially increased pulsation of the papillary arteries, by means of which it is possible to establish the differential diagnosis between the choked disc of cerebral tumors and that of kidney disease.

# MEDICAL RECORD:

*A Weekly Journal of Medicine and Surgery.*

WM WOOD & CO., 51 Fifth Avenue.

New York, September 2, 1899.

## OVERCROWDED PROFESSIONS.

IT would appear that the profession of medicine is not the only one that is overcrowded. The cry that there are too many doctors for the patients to be treated, that the income of the medical man is being reduced year by year in consequence, are such well-accepted facts that there is no room for argument to the contrary.

There is a melancholy comfort—we say melancholy because there is a pity with it—the clerical profession is now declared to be very much overstocked, as witness the following very direct and straightforward statement from a leading divine in the Hartford (Conn.) *Courant.*

The situation corresponds so exactly with the present condition of the ordinary practising physician that we quote the findings in full:

"The very highest average of employment given by the Church to its clergy is seventy-five per cent. of the total churches reported; one-fourth of the number always has been and is without pastoral help. And I assert positively that there is no good hope of change for the better. The Home Missionary Society and the Missionary Association have done and are doing their utmost to help needy churches, and, in spite of all, the last ten years gives us only seventy-four and one-half per cent. of the churches which are able to support a minister.

"This is the cardinal fact in the discussion and must be fairly faced in any honest attempt to seek the truth. And, as I have said, this fact gives the Church five hundred surplus ministers to date. So that the public may have all the facts, I make the following assertions as boldly as I can:

"First—That it is not possible for the theological seminaries to introduce young men into the ministry without driving out an equal number of men who are in work.

"Second—That there are a large number of men of the highest qualifications who cannot secure a pastorate in existing conditions.

"Third—That the appeal for financial aid for the seminaries on the ground that an increase of educated ministers is a necessity at the present time is an attempt to obtain money under false pretences.

"Fourth—That the present policy of purchasing impecunious students to fill the seminaries is an outrage on decency and justice. If men who study law or medicine must pay for the privilege, and the best men do it and honor their profession by their manliness, why should divinity offer free tuition, rooms, light and heat, and even, if that is not enough, lend or give money to destroy the manliness of the students, when many of the best workers the Church has are standing idle in the market-place with empty pockets and aching hearts?

"If there is one order of men who more than another should face all the facts and their consequences it is the Christian ministry. I ask them to do so in these premises."

It will be curious and interesting to note how our good friends will undertake to remedy the evil. Will it be to deter young men from studying theology for the present and give such as are so far and so inextricably in the harness a chance to live? The medical profession has tried that for many years and has signally failed. It is difficult to persuade a young man entering any learned calling that he is not destined to succeed when the ordinary run of his fellows fail. He always seizes the exception rather than the rule, and rarely finds out his true position until it is too late. To "waste sweetness on the desert air" is never thought of at the start. We are sorry accordingly for the young ministers who are eagerly waiting their chances. The end may be that they will be compelled to preach free on the street corners, and thus match the young doctor who gives so much advice gratis in the clinic room. In each case the public will have the best of excuses for allowing both minister and doctor to get their livings as best they may.

## THE CLINICAL MANIFESTATIONS OF ULCERATIVE ENDOCARDITIS.

INFLAMMATION of the endocardium may arise from a variety of causes, mostly toxic or bacterial, and the nature and the intensity of the morbid process will vary with the character of the causative agent. There may thus result any degree of inflammation, simple, proliferative, verrucose, polypoid, villous, purulent, ulcerative, and the clinical manifestations will vary accordingly. Apart from the residual valvular disease there is always danger in the proliferative forms of endocarditis of the occurrence of multiple embolism, which in the ulcerative variety is prone to be infective and usually terminates fatally. In a recent monograph Ebstein (*Deutsches Archiv für klinische Medicin*, B. 63, H. 3 u. 4) analyzes ten cases of ulcerative endocarditis that have come under his observation, and as a result of his study he finds that the course of the disease may be acute, subacute, or chronic, although the clinical manifestations are not correspondingly of definite constancy. The earlier, other things being equal, severe cerebral symptoms appear, the more rapidly the disease progresses toward a fatal termination. The classical indications of the malignancy of an existing endocarditis involving the heart-valves do not reside

in any peculiar character of the local or cardiac symptoms, but in the grouping of the general manifestations. Of most significance is the course of the fever, which is not characterized by temperature of especial elevation, but rather by wide fluctuations and an otherwise wholly atypical curve, often of inverted type. If under these circumstances endocarditic changes are not discoverable, nor others capable of accounting for the fever, the clinician will, as is not rarely the case, be compelled to content himself with a diagnosis of cryptogentic septico-pyæmia. Should, however, one or even more conditions be present to which the fever can be attributed, the difficulties in the way of a correct interpretation may be considerable or even insurmountable. The occurrence of one or more initial chills is not sufficient basis for a diagnostic conclusion; nor can the presence of metastatic abscesses or of infarction of embolic origin be diagnosticated with any certainty from frequently recurring chills, whether more or less typical or wholly irregular, atypical, and erratic. Even numerous chills recurring almost daily for weeks cannot be looked upon with certainty as a diagnostic criterion of the presence of metastatic abscesses resulting from ulcerative endocarditis; nor can they be considered as a certain sign of the pyæmic form of the disease. This condition may be suspected only when metastatic suppuration is detected in conjunction with other distinctive phenomena. A diagnosis of the typhoid form of ulcerative endocarditis is permissible only when it can be shown that other morbid processes capable of causing a typhoid state independently of ulcerative endocarditis are not present. Even then it may not be clear whether the typhoid state is only part of the general intoxication (or of its action on the brain) or is dependent upon material injury of the brain in consequence of intracranial metastatic suppuration. Under such circumstances conclusive information may sometimes be derived from bacteriological examination of the blood, or from study of the disease products of the morbid process (as of the fluid obtained by lumbar puncture), or from a knowledge whether or not suppurative processes are taking place within the body.

## A FATAL CASE OF BENZENE POISONING.

Poisoning with benzene is so rare and the resulting symptoms so variable that a case characterized especially by the irritant effects of the substance upon the structures and organs with which it came in contact, by the absence of narcotic effects, and by the toxic effects on the great nerve centres, as manifested by embarrassed breathing and circulation and high temperature, seems worthy of record. Spurr (*Lancet*, June 3, 1899) has reported the case of a woman, twenty-six years old, who had suffered from epilepsy since the age of eighteen, and who had also slight chronic bronchitis. Under treatment for eighteen months the epileptic attacks had become much less frequent, although irritability and depression were marked at times, and threats of suicide had been made. On one occasion a sister of the patient, hearing the latter moving about in her bedroom early in the morning, thought the latter had had a fit, and on investigation noticed a strong smell of benzene in the room and saw lying on the floor an empty bottle which she knew had contained benzene. The patient admitted having taken the stuff, and a strong emetic of mustard and water induced free vomiting. There was, however, severe burning pain in the stomach, throat, and mouth, without loss of consciousness. There was also great difficulty in swallowing together with a sense of extreme weakness. It is estimated that an ounce of benzene had been swallowed.

The tongue was white, as if smeared over with paint, and the fauces were swollen and presented a similar appearance. During the day there was slight diarrhœa. On the following day the patient was much worse. She had had a bad night, the pain in the throat and stomach being very great. Difficulty in swallowing had been marked, and the breathing short and rapid. The pulse rose to 40, and the temperature to 103° F. Loud moist râles could be heard over the upper part of the chest, with slight dulness on percussion, and crepitation over the lower lobes. There was still extreme tenderness on palpation in the region of the epigastrium. A hypodermic injection of strychnine was given and rectal feeding was suggested, but as the patient became unconscious and was practically moribund before preparations could be made, these were not carried out. On the following day the patient became comatose; the pulse, which was small and thready, rose to 160, the respirations to 48, and the temperature to 105° F. Death resulted fifty hours after the taking of the poison.

On examination, twenty-eight hours after death, the cadaveric rigidity was well marked. The liver, kidneys, and spleen were congested, the last being enlarged and weighing fifteen ounces. The stomach was empty and contracted. Its mucous and submucous coats were thickened and intensely inflamed, the affected area having almost the appearance of dark, crimson velvet. This inflammatory condition extended over the greater part of the internal surface of the viscus, the cardiac extremity and a band an inch or an inch and a half wide along the greater curvature escaping. The œsophagus was also inflamed almost throughout its entire length, and the duodenum throughout its entire circumference for the first three inches. There were several erosions of the mucous membrane of the duodenum, but the remainder and a part of the jejunum were inflamed in patches, which were mostly situated about the projections of the valvulæ conniventes. The remainder of the intestinal tract was healthy. The lower lobes of the lungs were congested, and crepitated imperfectly, and on section showed a dark red color, with exudation of blood-stained, frothy serum on pressure. The bronchi and larger tubes contained puriform matter. The brain and meninges were congested, and the meningeal vessels were greatly engorged.

**Beri-Beri.**—Two cases of beri-beri have been discovered at Biloxi, Miss., by the sanitary inspector of the State board of health.

## News of the Week.

**Examinations for the Marine-Hospital Service.**—A board of officers will be convened at the Service Building, 378 Washington Street, New York City, Wednesday, October 4, 1899, for the purpose of examining candidates for admission to the grade of assistant surgeon in the United States Marine-Hospital service. Candidates must be between twenty-one and thirty years of age, graduates of a respectable medical college, and must furnish testimonials from responsible persons as to character. The usual order of the examination is (1) physical, (2) written, (3) oral, and (4) clinical. Successful candidates will be numbered according to their attainments on examination, and will be commissioned in the same order as vacancies occur. Upon appointment the young officers are, as a rule, first assigned to duty at one of the large marine hospitals, as at Boston, New York, New Orleans, Chicago, and San Francisco. After five years' service, assistant surgeons are entitled to examinations for promotion to the grade of passed assistant surgeon. Promotion to the grade of surgeon is made according to seniority, and after due examination as vacancies occur in that grade. Assistant surgeons receive $1,600, passed assistant surgeons $2,000, and surgeons $2,500 a year. When quarters are not provided, commutation at the rate of $30, $40, or $50 a month, according to grade, is allowed. All grades above that of assistant surgeon receive longevity pay, ten per cent. in addition to the regular salary for every five years' service up to forty per cent. after twenty years' service. The tenure of office is permanent. Officers travelling under orders are allowed actual expenses. Further information, or invitation to appear before the board of examiners, may be obtained by addressing the Supervising Surgeon-General, United States Marine-Hospital service, Washington, D. C.

**The Plague** continues at Oporto, and the situation in that city is reported to be grave. The cases are chiefly of the pulmonary variety, which is especially fatal. Up to August 29th there had been fifty-seven cases and twenty-one deaths from the disease—not a large number, certainly; but the apprehension arises from the knowledge that the sanitary condition of the city, like that of most others in the Iberian peninsula, is exceedingly bad. There is a possibility of disturbances owing to the outcry from merchants and the popular indignation against the sanitary cordon that has been established to prevent the spread of the disease. The Commercial Union of Oporto has requested that Robert Koch be called to the city to make a bacteriological investigation, in order to set at rest, one way or the other, the doubts that are expressed as to the nature of the disease. It is now admitted that the disease in Astrakhan is the bubonic plague, and the Duke of Oldenburg, president of an association formed to combat the epidemic, has gone there with several physicians and bacteriologists. It is stated that an international sanitary commission will meet at Brussels on September 4th, to discuss measures for preventing the further spread of the plague. In the mean while the usual sure cure is announced, this time by a Sicilian physician who claims to have discovered a curative and prophylactic serum.

**Yaws** is prevailing to an unusual extent in Jamaica this summer, especially in the Yallahs district. The island is also suffering from a prolonged drought.

**The State Board of Charities.**—Governor Roosevelt has appointed Eugene A. Philbin, of New York City, to succeed John Vinton Dahlgren, deceased, as a member of the State board of charities. Mr. Philbin is a member of the Bar Association and has been associated with many charitable institutions.

**The Hurricane in Porto Rico.**—The official report of the Porto Rico board of health shows that there have been twenty-three hundred and twelve burials of victims of the recent hurricane. In addition to that, one thousand families are missing, together with their houses. The report states that the number of destitute persons is two hundred and fifty thousand. It is estimated that one thousand tons weekly of beans and rice will be required to feed the destitute for the next four months, until the new crops are grown.

**The American Association for the Advancement of Science.**—The annual meeting of this association was held last week at Columbus, Ohio. The following officers were elected: *President and Treasurer*, Robert Simpson Woodward, dean of the School of Applied Science of Columbia University, New York, and professor of mechanics in the same university; *Permanent Secretary*, L. O. Howard, of Washington, government entomologist; *General Secretary*, Charles Baskerville, of Chapel Hill, N. C.; *Secretary of Council*, William Hallock, of New York. The next meeting will be held in this city, June 25–30, 1900.

**Compulsory Notification of Tuberculosis.**—The Michigan State legislature at its recent session passed an act requiring physicians to report to the health office all cases of pulmonary tuberculosis, classing the disease as contagious. Physicians very generally refused to obey the law, and the health board had a warrant issued against Dr. Ernest L. Shurly, of Detroit, in order that a test case might be tried. The trial ended with Dr. Shurly being found guilty and fined $50 and costs. The case will be carried to the Supreme Court for final decision.

**Typhoid Fever in Boston.**—It is stated in the New York *Times* that an increase of about thirty-six per cent. in cases of typhoid fever in Boston is shown this month over the same period in 1898, and the authorities are bestirring themselves in the matter. An active search is being made by the board of health for the source of contagion in Jamaica Plain and Roxbury, which have added a number of cases to those at the hospitals.

**Successor to the Women's Medical School.**—The medical school attached to the New York Infirmary for Women and Children was discontinued this year, after a long and prosperous career, the managers hav-

ing decided that the facilities for medical coeducation in this city were now all-sufficient for the needs of any woman student. The infirmary, however, is to be continued, and the material there will be utilized for clinical instruction. In order that this material may be used to the best advantage, the officers of the infirmary will give a number of special courses in laboratory work and practical medicine to both graduates and undergraduates during the year. The number of patients treated in the dispensary, the infirmary, and their own homes was last year 17,314.

**Yellow Fever in Mexico.**—Yellow fever has spread from Tuxpan to a number of smaller towns along the coast between that place and Tampico, and the daily number of deaths is very large. In Tuxpan there is no decrease in the daily number of new cases. The deaths there number about ten a day.

**An Office Thief** is at present "working" the physicians in this city. He is described as a mulatto, apparently about twenty years of age. He calls at the office, sees the doctor, and gives him an address where a patient is said to be suffering. After the victim has gone off on his errand of mercy the man returns and says he will wait for the doctor's return. The servant, having seen him before, regards him as a regular patient and admits him, and he selects what articles he regards as the most valuable and the most portable and decamps.

**Enforcing the Vaccination of School Children.**—Complaint has been made to the New York State board of health by the health department of New York City that little has been done outside of the boroughs of Manhattan and the Bronx to obey the vaccination law which provides for the vaccination of all school children. The State board insists upon literal obedience in this respect, for the law is mandatory in its provisions, and unless the boards of education in the boroughs of Queens, Brooklyn, and Richmond comply with the law, the public schools will, it is asserted, be closed.

**The New York State Medical Association.**—The sixteenth annual meeting of this society will be held in the hall of the New York Academy of Medicine on October 24, 25, and 26, 1899. The preliminary programme contains the titles of upward of thirty papers to be read, in addition to a number to be contributed to the set discussion on "typhoid fever." On the evening of the 25th, a reception will be given by the association, at the New York Academy of Medicine, to Dr. W. W. Keen, of Philadelphia, president of the American Medical Association. The secretary of the association is Dr. C. E. Denison, 215 West Thirty-fourth Street, and the chairman of the committee of arrangements Dr. F. H. Wiggin, 55 West Thirty-sixth Street. A large attendance is expected.

**Smallpox in New York State.**—Circulars have been sent out by the State board of health, calling attention to the prevalence of smallpox in several places in the western part of the State, and stating that the spread of the disease at the present time, as was the case a year ago, may be attributed in a large degree to the fact that many cases of smallpox were mistakenly diagnosed as chickenpox. It is suggested that the local boards of health adopt and enforce rules requiring that all cases of supposed chickenpox be reported promptly to them, in order that such cases may be kept under observation and quarantined, if necessary, until the diagnosis is definitely established. The board is meeting with some difficulties in controlling the disease in consequence of the opposition of the ignorant and the vicious. The health officer of Niagara Falls has been sued for damages, having quarantined a smallpox patient, and the antivaccinationists are improving the opportunity by conducting an agitation against him in the public press.

**A Revived Journal.**—The *St. Louis Courier of Medicine* has been resuscitated after a slumber of ten years and a half. Its first life lasted ten years, from January 1, 1879, to January 1, 1889. We trust its new term of existence will be much longer than its first, and it doubtless will if the subsequent numbers are as good as the one before us. The journal is under the editorial charge of Dr. C. R. Dudley, assisted by Drs. J. Grindon, E. F. Smith, and W. A. Shoemaker.

**The Transportation of Dead Bodies on Railroads.**—A suit is about to be instituted by a resident of Hoboken against the Delaware, Lackawanna, and Western Railroad Company. On July 13th a child of the plaintiff died of membranous croup. An undertaker placed the body in an hermetically sealed casket and conveyed it to the station of the Delaware, Lackawanna, and Western Railroad, to be taken to another town for burial. The station agent, however, refused to accept it on behalf of the company or even to allow the undertaker on his own responsibility to place it in the baggage car.

**"Revista Ibero-Americana de Ciencias Medicas"** is the name of a new quarterly journal, the first number of which appeared in Madrid in March, 1899. The editor-in-chief is Dr. Luis Marco. The two numbers which have thus far appeared give promise of a genuine acquisition to medical periodical literature. The original articles and reviews are of a high order and written on subjects of practical scientific interest.

**Board of Health of Porto Rico.**—A general order was issued the latter part of June constituting a superior board of health for Porto Rico, the authority of which will extend throughout the island, and to which all local boards of health will regularly report. The board is composed of six members as follows: Major John Van R. Hoff, surgeon United States army, chief surgeon of the department; Surgeon Arthur H. Glennan, United States Marine-Hospital service; Surgeon F. W. F. Wieber, United States navy; Dr. George G. Groff, Dr. Gabriel Ferrer, Dr. Ricardo Hernandez. The chief surgeon of the department will act as president of the board, and Dr. George G. Groff is appointed secretary and treasurer.

**Dr. Lambert Lack's Cancer Theory.**—In a note to *The Lancet*, disclaiming any responsibility for the newspaper reports of his alleged discoveries concerning

the nature of cancer, Dr. Lambert Lack takes occasion to state briefly just what he has done. He had long been impressed, he said, by the belief that the epithelial cells of cancer are themselves the sole infective agents; that this cancer epithelium is practically normal epithelium, only out of place; and that from the very commencement of the cancer it is growing in the lymph spaces. He thought from this that if the normal epithelium by some accidental means should obtain entrance into the lymph spaces it would find no barrier to its continued growth and would produce all the phenomena of cancer. Up to the present time he has performed but a single experiment to test this view. He obtained an emulsion of the epithelial cells from the healthy ovary of a healthy rabbit and placed it in the animal's peritoneum. The animal died fourteen months afterward, and on examination masses of growth were found in the abdominal and thoracic cavities having the characteristic features of typical ovarian cancer. Experiments will be carried out to confirm and extend these results, but until these have been completed, he says, no general conclusions can be drawn.

**Wholesale Food Poisoning.**—Between eighty and ninety London school children were recently poisoned by food taken at a picnic at Blackheath. The symptoms were those of severe ptomain poisoning, but happily no deaths occurred.

**Christian Science in Chicago.**—An association has been formed in Chicago for instituting legal proceedings against a Christian scientist named Dowie, at whose place several deaths have occurred recently as a result of neglect of medical treatment.

**Eucalyptus Plantations in Cuba.**—It is reported that an attempt will be made in several of the most malarious districts of Cuba to effect a sanitary betterment by means of eucalyptus plantations. A number of trees have been planted in and about Santiago, and further experimentation is contemplated.

**A New Hospital at Des Moines.**—A new hospital under the management of members of the Methodist church is to be established at Des Moines, Iowa. A site has been given, and money for construction and endowment is now being raised. It is hoped to begin work on the buildings within a few months.

**A Sanatorium for Consumptives in Illinois.**—The Illinois Society for the Prevention of Consumption is preparing plans for a State sanatorium for consumptives, which it will ask the next legislature to build. The Illinois State board of health has been investigating the advisability of such an institution, and reports favorably. The legislature will be asked for an appropriation of half a million dollars for the construction of the sanatorium.

**City Aid to Private Charities.**—The comptroller of this city has announced himself as opposed in general to the granting of appropriations by the city government for the support of charitable institutions not under the control of the city. He will act on the lines suggested by the recent report of the State Charities Aid Association, and will recommend that the board of estimate and apportionment ask the legislature to repeal all mandatory laws prescribing the amounts to be given to institutions, and to give the board full power to deal with all the institutions. To back up his recommendation, he will submit a complete report of the work of the various charitable organizations. If the comptroller gains his object several medical institutions classed as charities will be unpleasantly affected.

**The Continental Anglo-American Medical Society.**—The members of the Continental Anglo-American Medical Society present at Portsmouth during the annual meeting of the British Medical Association lunched together on Wednesday, August 2d, at the Pier Hotel. Prof. William Osler (Baltimore), one of the vice-presidents of the society, occupied the chair. The guests included Sir William Broadbent, Bart.; Sir R. Douglas Powell, Bart.; Prof. Clifford Allbutt, Dr. Burney Yeo, Dr. Mitchell Bruce, Mr. Malcolm Morris, Dr. St. Clair Thomson, Dr. Frederick Roberts, Dr. Watson, Dr. C. C. Claremont, and Dr. Cholmeley. Dr. Ward Cousins and Dr. Dawson Williams were prevented by pressure of business from being present. The members present were Dr. T. E. Charles (Rome), Dr. Johnston-Lavis (Beaulieu), Dr. D. W. Samways (Mentone), Dr. Cree (Paris), Dr. Hamilton (Bordighera), Dr. Freeman (San Remo), Dr. Gairdner (Naples), Dr. Warden (Paris), Dr. Robinson (Paris), and Dr. Bull (Paris), honorary secretary of the society. The toasts of "The Queen" and of "The President of the United States" were proposed by the chairman. Sir William Broadbent then gave "The Continental Anglo-American Medical Society," and spoke of the advantage to practitioners in England of being personally acquainted with medical men practising on the continent, to whom they often had to send patients. Dr. Samways (Mentone) replied for the society. Dr. T. Edmonston Charles (Rome) then proposed "Our Guests." The society, he said, might be congratulated on so distinguished a company of medical men having accepted its invitation to be present. Dr. Mitchell Bruce responded for the guests. Prof. Clifford Allbutt then proposed "The Health of the Chairman," and observed that one of the chief indications of merit and success in a professor was the men of note who had been turned out from his department during his professorship. So judged, Professor Osler might well be congratulated. The chairman, in replying, said that the manner in which he had been received and treated in the States had made him feel that his home was there. But, after all, he was a Canadian. No man could get away from his early associations. He was an American-Canadian, and there was but one thing better, and that was to be an Anglo-American Canadian.—*The British Medical Association.*

**Dr. Mary Walker.**—Our esteemed contemporary *The Medical Press*, which is always very superior and occasionally somewhat mixed when commenting on

American doings, or supposed doings, tells us of "a curious professional incident" which it says is reported from New York. "The tale is that Dr. Mary Walker, a well-known citizen, was desirous of finding out what her appearance would be when dead. She accordingly had herself photographed when laid out as she would be for the grave. This strange picture is now being published broadcast over New York, so says *The Morning Leader*. The information is added that flowers are strewn over the dress (*sic*) in which she lies, and on the lapel of her jacket is a bronze medal, which Dr. Walker says was presented to her by Congress shortly after the Civil War." This is the text, and now for the moral, in which this ever-delightful editor is as bathetic as he is superior: "Of course, as every one knows, on this side of the Atlantic any attempts to attain publicity by methods that savor of self-advertisement are rigorously condemned by an unwritten code of laws. In America, however, there are no such restrictions," etc. The humor of this is too exquisite to spoil by any explanation to our calm contemporary.

**Navy Department,** Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending August 26, 1899. August 21st.—Medical Inspector C. U. Gravatt ordered to duty at the New York navy yard as member of board of medical examiners, September 5th; Passed Assistant Surgeon C. F. Stokes detached from duty as member and recorder of board of medical examiners at the New York navy yard, September 5th, and ordered to continue on duty at the naval hospital, New York. August 22d.—Passed Assistant Surgeon M. S. Guest ordered to the Boston navy yard; Pharmacist S. Englander detached from the Mare Island navy yard, and ordered to the New York navy yard; Pharmacist L. R. G. Lewis detached from the New York navy yard, and ordered home and to wait orders.

**Insanity in England.**—The recently issued annual report of the English commissioners in lunacy shows a great increase in insanity in England and Wales. On January 1st of the present year there were 105,086 persons adjudged insane, an increase of 3,114 over the previous year. The increase occurred among those of all social grades, being greatest, however, among paupers. It is thought a government inquiry will be made into the causes of this increase.

**Suicides in New York City.**—The report of the board of health for the quarter ending March 31st shows that during the first three months of the year 162 persons committed suicide, 55 of them by taking carbolic acid, 34 by shooting, 30 by inhaling gas, 17 by hanging, and the others by stabbing, drowning, leaps, and poisons of various kinds. Of the 162 suicides 117 were men and 45 women; 62 were natives of Germany, 49 of the United States, 10 of Ireland, and the others were of various nationalities.

**Lead Poisoning from Driven-Well Water.**—The Massachusetts State board of health has recently held a public hearing at Lowell, Mass., regarding lead poisoning from driven-well water. It appears from the report that in every one of seventy-four samples of water examined a dangerous amount of lead was found. Physicians in Lowell have recently reported forty cases of poisoning of varying degrees of severity coming under their observation. The removal of lead pipes in houses through which water is obtained for drinking or cooking purposes was urged. It was further stated that a filter, similar to one now in use in Lawrence, might be built as a protection to public health.—*Boston Medical and Surgical Journal.*

**Dr. James Cuming,** of Belfast, died on August 28th at the age of sixty-eight years. He received his degree of M.D. from the University of Ireland in 1855.

**Obituary Notes.**—Dr. Max Thorner, of Cincinnati, was found dead in his bath-room on August 27th, death having resulted from disease of the heart. Dr. Thorner was thirty-nine years of age, and was graduated in medicine from the University of Munich in 1884. He was one of the foremost laryngologists in Cincinnati, and was professor in that branch at the Cincinnati College of Medicine and Surgery. He was a member of the American Laryngological, Rhinological, and Otological Society, and chairman of its western section, and was elected a member of the American Laryngological Association at the annual meeting in Chicago last May.—Dr. Harris, of Bruceville, Tex., was fatally shot as the result of a political dispute on August 24th. He was a graduate of the medical department of Vanderbilt University in the class of 1879.—Dr. John J. Linson, of Tarrytown, N. Y., died suddenly on August 27th, at the age of seventy-two years. He was born in this city and was graduated in medicine from the New York Medical College in 1856. In the Civil War he served with the Sixth New York Heavy Artillery as assistant surgeon, and later was detailed as surgeon for the provost marshal's office at Tarrytown. At the end of the war he established himself in practice in Tarrytown. He was for three years president of the Westchester County Medical Society and also was a member of the New York State Medical Society. A widow and six children survive him.—Dr. R. B. Loryea, of Manning, S. C., died August 23d at Tryon, in the mountains of North Carolina, from cardiac exhaustion induced by over-exertion. Early in the morning he started for a long tramp. He did not know the route, and was directed as to the paths he was to take, but lost his way. At night he was found dead at a distant place on the mountain over which he had wandered the whole day.—Dr. Andrew Martin was killed by lightning on August 26th, at his home near Mount Joy, Pa. He was sixty-six years old, and was a graduate of the University of Michigan and of Jefferson Medical College.—Dr. James F. Feeley, of Brooklyn, died suddenly on August 30th. He was born in London in 1844 and was graduated from the New York University Medical College in the class of 1865. He was visiting surgeon to St. Catherine's Hospital, Williamsburg.

# Reviews and Notices.

STATE OF CONNECTICUT; Regulations for the Guidance of Surgeons of the Connecticut National Guard, and Post-Surgeons, for Medical Examination of Recruits for the Connecticut National Guard. Middleton, Conn.: Pelton & King. 1899.

THIS small volume of thirty-six pages was prepared by J. Francis Calef, M.D., Surgeon-General Connecticut National Guard. Directions regarding methods of examination and the qualifications necessary for admission into the Connecticut National Guard are given. The disqualifications to admission into the United States army in time of peace are compared with those for the Connecticut National Guard. The articles of the Geneva Convention for the care of the wounded in armies in the field are given. The work is intended for the use of the medical officers in the Connecticut National Guard, and is excellently adapted for that purpose.

ENCYCLOPÄDIE DER THERAPIE, herausgegeben von OSCAR LIEBREICH, Dr. Med., Geheimer Medicinalrath, o.ö. Professor der Heilmittellehre an der Friedrich-Wilhelms-Universitat, unter Mitwirkung von MARTIN MENDELSOHN und ARTHUR WÜRZBURG. Dritter Band, 1 Abtheilung. Berlin: August Hirschwald. 1899.

THIS part of Liebreich's "Encyclopædia of Therapeutics" carries the titles from Mammaneuralgie to Pharyngitis. Among the more important of the articles here treated of are measles, diseases of the rectum, massage, melancholia, menstruation, migraine, middle-ear diseases, morphine, diseases of the muscles, myelitis, myxœdema, nasal affections, sodium and its salts, neurasthenia, renal diseases, nicotine, habitual constipation, syncope, ophthalmia, the ophthalmoscope, sprains, diseases of the pancreas, paranoia, pericarditis, peritonitis, appendicitis, and the plague. The treatment of these and innumerable other subjects is excellent, the articles being most concise yet complete in all essential particulars.

AN ESSAY ON THE NATURE AND THE ANOMALIES OF REFRACTION. By F. C. DONDERS, M.D., Late Professor of Physiology and Ophthalmology in the University of Utrecht. Revised and Edited by CHARLES A. OLIVER, A.M., M.D. (University of Pennsylvania), one of the Attending Surgeons to the Wills Eye Hospital. With portrait and other illustrations. Philadelphia: P. Blakiston's Son & Co. 1899.

THE editor of the translation of Donders' essay has certainly conferred a favor on the younger American and English workers in the field of ophthalmology, by putting it before them in a form to be easily read and comprehended. It is, indeed, as stated by the editor, remarkable to note "to what slight extents the fundamental principles laid down by the talented author in the pages of his almost unique brochure have suffered correction, alteration, and conversion during the thirty progressive years that have followed its publication." The pith of the whole subject is contained within the eighty pages of this small volume. The text is in numbered paragraphs, each of which is in the nature of an aphorism. This book, which contains a portrait of the talented author, should be in the possession of every ophthalmologist.

THE CRYSTALLINE LENS SYSTEM: Its Embryology, Anatomy, Physiological Chemistry, Physiology, Pathology, Diseases, Treatment, Operations, and After-Changes. With a Consideration of Aphakia. By LOUIS STRICKER, M.D., Cincinnati, Ohio. 1899.

IN this volume of five hundred and ninety-nine rather closely printed pages, four hundred and fourteen are devoted to the consideration of the crystalline lens system, and one hundred and eighty-five pages to bibliography and index. The bibliography dates back to the year 1532, and appears to be quite complete up to the early part of 1898. There are no illustrations. The work does not represent the results of original research on the part of the author, but is a creditable digest of the views of all the writers of repute on the subject, up to the time of the completion of the manuscript. The text is divided into five parts, of which Part I. is devoted to a discussion of the normal lens system. Part II. deals with the pathological lens system, and is very complete. Part III. is occupied in "A Systematic Consideration of the Causes, and a Clinical Description of All the Diseases of the Crystalline Lens"; Part IV., "The Therapy of the Diseases of the Lens"; Part V., "The Aphakic Lens." The consideration of the subject is most exhaustive. Nothing of importance has been overlooked, and due weight has been given to each division of the work. The writer has given expression to his thoughts in a clear manner, free from repetition and ambiguity. The book is one for the ophthalmologist only. The author has recognized the value of and has adopted a classification of topics, so arranged that the information desired may be obtained in the least possible time. He has added a suitable index. The volume represents a very large amount of well-classified labor. It is replete with facts, and is an excellent work for reference. Its worth is such that it should be in the hands of every ophthalmic surgeon.

A TREATISE ON "UNRIPE" CATARACT. By WILLIAM A. MCKEOWN, M.D., M.Ch., surgeon to the Ulster Eye and Throat Hospital, Belfast; member of the Senate of the Royal University of Ireland; lecturer on ophthalmology and otology, Queen's College, Belfast. Illustrated by nine plates containing sixty original drawings. London: H. K. Lewis. 1896.

THIS work is comprised of one octavo volume of two hundred and two pages, is printed in large type, and is abundantly illustrated. The operation for the removal of cataract is discussed in a relatively brief manner, the author's whole argument being one to establish his view that immature cataract may be removed by operation with results equal to those obtained by extraction when the cataractous lens is mature. The procedure, which in the author's hands has made the operation successful, is irrigation, intra-capsular by means of a hollow needle, after the corneal incision has been made, also at the wound and in the anterior chamber. A new classification of cataract is advocated. Directions for the examination of the eye and for the preparation of the patient for operation are given in detail. "Post-operative Incidents and Treatment" are discussed. A statement of cases occupying forty-five pages is included. Appendix A is devoted to a discussion of the relative merits of the simple and combined operation for cataract, in which the decision is in favor of the latter. Appendix B is devoted to extracts from an address by the author. The work is of interest to the ophthalmologist. The view of the author regarding classification will be opposed by many. The results in the one hundred and fifty-five cases reported substantiate the claims of relative safety for the operation. The visual results, however, possibly because of the few discissions made, are not up to those reported by some other operators.

MANUAL OF BACTERIOLOGY. By ROBERT MUIR, M.A., M.D., F.R.C.P. Ed., Professor of Pathology, University of Glasgow, and JAMES RITCHIE, M.A., M.D., B.Sc., Lecturer in Pathology, University of Oxford. Second edition. New York: The Macmillan Company. 1899.

THIS is a concise yet sufficiently thorough treatise on bacteriology, in which any one desiring to refresh and amplify his knowledge of this newest and most promising of the medical sciences will find all necessary information. The term bacteriology, as applied to this general subject, is an unfortunate one, for, taken in its literal sense, it leaves out of consideration many microparasites (cocci, for example) which are not bacteria, and also all the animal micro-organisms. The latter difficulty the authors of the present work have met by treating of malaria and dysentery in an appendix. The early chapters are, as usual in such works, devoted to general morphology and the technique of culture, staining, and inoculation, after which come chapters on the non-pathogenic micro-organisms and the relation of bacteria to disease. Then the microbes associated with special diseases are described, and finally the question of immunity is discussed in the closing chapter. In an appendix, in addition to the diseases already mentioned, there is a discussion of smallpox and vaccination and rabies, the nature of the causal organisms of which is not yet determined. This little work is written in a clear and pleasing style, the size of the book is convenient for holding in the hand, its weight is little, and the illustrations are for the most part excellent.

# Society Reports.

## THE BRITISH MEDICAL ASSOCIATION.

*Sixty-Seventh Annual Meeting, Held at Portsmouth, August 1, 2, 3, and 4, 1899.*

(Special Report to the MEDICAL RECORD.)

### SECTION OF SURGERY.

*Second Day—Thursday, August 3d.*

(Continued from page 323.)

**Bullet Wounds.** — MR. CLEMENT LUCAS reported two cases of bullet wounds, one of the head and one of the neck, in which the bullets were localized by means of the *x*-rays. The first case was that of a child, aged ten years, who was shot in the back of the head, the bullet entering the upper part of the occipital bone on the right side. All the general signs of presence of the bullet in the cranium existed, but there was no interference with any motor tract and no signs of localization. A skiagram showed the bullet in two portions, one near the aperture, and another two inches farther on near the vertex. The child was trephined, and both pieces were removed. The patient made a good recovery. Mr. Lucas pointed out that one of the points of interest was the presence of two pieces of the bullet as shown by the skiagram. Without the *x*-rays the surgeon, having found the first fragment, would probably have rested satisfied with its extraction, and the remainder of the bullet would have been left in the cranial cavity. In the other case a woman, aged thirty-six years, the mother of the above (both having been shot by the woman's husband at the same time), a bullet wound was present on the right side of the neck, one and one-half inches below the mastoid. The skiagram showed the bullet lying to the left side of the body of the second cervical vertebra. In the same position, by the mouth a hard swelling could be found. Mr. Lucas cut down on it through the mouth, but the swelling turned out to be an exostosis springing from the vertebra. An incision was then made along the anterior border of the sterno-mastoid, and the bullet itself was reached from without. The curious coincidence was pointed out of the existence of the exostosis close to the embedded bullet.

MR. DAMER HARRISSON related several cases illustrating the difficulty of localizing the bullet if the *x*-rays were not used.

On the other hand, MR. BUTLIN related two cases under his care, both chest wounds, in which an aperture of entry existed, but none of exit. The patients were most carefully examined by the *x*-rays, but with a negative result.

It was suggested that the bullets might have struck a rib, and dropped out again.

Mr. Butlin was of opinion, however, from the symptoms present, that the bullets were there.

**Operation for Cancer of the Jaw.**—MR. J. PAUL BUSH, of Bristol, read a paper on extensive operations on the jaws for malignant disease. In one case of a girl, aged fifteen years, the greater part of both superior maxillary bones was removed for spindle-celled sarcoma. She recovered well, and the photographs shown demonstrated how little deformity resulted. In another case, that of a man, aged sixty years, after preliminary ligature of both the lingual arteries, the tongue, body of lower jaw, and all infected glands were removed. When the structures connected with the hyoid bone were cut through, great difficulty of breathing, due to falling back of the epiglottis, occurred. A suture was passed through the stumps of these structures and the entrance to the trachea was held open. But it was necessary to keep up this traction for six hours, as when it was relaxed asphyxia recurred. The patient recovered. Mr. Bush insisted on the propriety of feeding for a lengthy period by means of a short, wide tube. He believed the great cause of sepsis in these cases was due to food getting into the mouth cavity too soon.

MR. DAMER HARRISSON, of Liverpool, asked whether the patient had experienced any difficulty with the saliva. He related a case in which Mr. Alexander removed the whole lower jaw, skin included, the man having been now eight years free from recurrence. In this case a tray with a tube leading to a bottle in the pocket had to be worn to catch the saliva.

MR. BUTLIN thought we were too desponding with regard to these operations. These cases should not be viewed with regard to dissemination and secondary growths, but considered as essentially local, and to be treated by radical removal. He spoke of the large adoption of these views by German surgeons, and said that though the mortality was high the results were good. He had also, as in Mr. Bush's case, met with difficulty in breathing and from a similar cause. He mentioned one case in particular, in which he regretted not having done a preliminary tracheotomy, because, although during the operation a suture through the stump immediately relieved the symptoms, the patient died suddenly from asphyxia a week later, owing to the suture giving way when no help was at hand.

MR. CLEMENT LUCAS had found the asphyxial symptoms remedied by suturing the stumps of the muscles attached to the hyoid bone to the skin.

MR. BUSH in reply said he had found no trouble with regard to the saliva. He concluded that the parts in front of the hyoid bone eventually became adherent to the skin. But he had no idea that the fixation thus afforded was efficient.

**Prevention and Treatment of Syphilis in the Navy and Army.**—DEPUTY INSPECTOR-GENERAL E. E. MAHON, of the royal navy, opened the discussion. He reviewed the statistics of venereal disease in the navy from 1860 to 1897, that is, before and during the application of the so-called Contagious Diseases Act of 1866, and subsequent to its repeal in 1883. His conclusions were that during the application of the act the prevalence of syphilis was much diminished, while that of gonorrhœa was unaltered or increased. In the case of the statistics relating to gonorrhœa the apparent increase might have been due to the relaxation of the regulations relating to loss of pay, etc. While these regulations were in force many men suffering from gonorrhœa did not present themselves, if they could avoid doing so, for treatment. Although he had no doubt of the beneficial effect of the act, he thought it impossible to hope that it would ever again be enforced. Failing this, he believed that much might be done by encouraging sobriety, the provision of good naval barracks and recreation grounds, by giving good advice to young sailors, by the encouragement of early marriage, and, lastly, pensioners who during their service career had not suffered from ill health due to venereal disease should be given the preference in the distribution of posts open to them. As to the treatment of syphilis he believed in the prolonged and continuous administration of mercury, but of the intramuscular injection plan he had no personal experience.

MAJOR DICK, of Netley, pointed out that from 1880 onward the percentage of admissions for venereal disease compared to the total admissions for all causes was steadily increasing. Thus, of those sick in 1882, twenty-three per cent. were venereal; in 1892, thirty-one per cent., and in 1897 the percentage had risen to thirty-eight. That is, in 1897 in India,

of every one hundred sick soldiers thirty-eight were venereal. This he regarded as a striking commentary. Also the number invalided home until 1888 never reached one hundred in the year, whereas in 1897 it reached eight hundred and four, or nearly one-third of all cases treated in Netley—thus pointing to a greatly increased severity of the disease. As to the prevention, he thought that continence among a body of healthy young men, especially abroad, was not to be expected. So common had venereal disease become that the men lost all shame in having it. He believed in the careful hygiene of the individual, and in rendering his life in barracks as pleasant as possible. As to the women he was unprepared with any opinion, and asked for suggestions. With regard to treatment he applied pure carbolic acid locally and dressed with black wash, and gave mercury by the mouth or by inunction. He preferred either to intramuscular injection. The various parts of the body should be rubbed in rotation. Intramuscular injection should be left for those cases in which symptoms recurred after another course of treatment had been adopted. Great care should be taken of the condition of the mouth.

Dr. C. R. Drysdale believed that the statistics given were useless, as the cases should have been divided into syphilis, soft sores, and gonorrhœa, and that the inclusion of soft sores with syphilis invalidated the whole. He did not believe that gonorrhœa could arise *de novo;* it resulted from promiscuous sexual intercourse. Faithful husbands and faithful wives did not have it. If these diseases did not arise *de novo*, they might be stamped out by isolation. He believed the French system of supervision had utterly failed—that in Paris three or four thousand women were brought under police notice and forty or fifty thousand not. Here in this country the experience was that the Contagious Diseases Act or acts had failed; at the end of their term of application more gonorrhœa existed at the stations where they were in force than at the beginning. He thought that we had less syphilis here than on the continent because the individual looked after himself. What we wanted was voluntary hospital accommodation for venereal cases. In London, except the Lock Hospital and Workhouse Infirmary, no one wanted to receive venereal cases. He did not believe in the reports of the severity of the disease in the Indian troops; he had seen no severe cases at Netley. Why was there no venereal disease among the native troops in India? Because they married young. He proposed early marriage, with regulation of the number of offspring, that thereby the only objection to early marriage, *i.e.*, poverty, would be removed. He objected to intravenous and intramuscular injections as dangerous.

Major F. J. Lambkin considered that for prevention of venereal disease the Contagious Diseases Acts were absolutely necessary. As to treatment it should be continued for at least eight or twelve months. Under the older methods of treatment, that is, the administration of mercury in pills or mixtures, it was impossible to obtain a good result, as the patients, feeling well and seeing nothing wrong, neglected to take them. But a patient can come up once a week and receive an intramuscular injection. He had given twenty thousand injections with only one ill result—that was a small abscess in one case. He found the men readily presented themselves. He used a cream of mercury, lanolin, and carbolic oil. The administration was almost painless. He believed the injection treatment to be especially useful in the army, navy, and lower classes of civil life.

Major William Niven thought any measures adopted should be applicable to both sexes. It was unfair to coerce women and leave the men free. He considered washing, even after one or two hours, useful, and suggested a more liberal introduction of lavatories for washing. He was sure there was a great increase of venereal disease. As to the causes in India they were doubtful. It had been whispered that diseased women were purposely introduced by the natives. Then the conditions in India were peculiar. There one had to deal with a class of women not considered disgraceful, but as a caste with its own privileges. These women must be looked on as a necessary factor of civilization. How was it that, due to moral agencies, the morals of soldiers in other ways had improved, yet venereal disease was on the increase? He suggested that a material purity party should be established to work alongside the spiritual purity party.

Dr. G. Ogilvie drew attention to the similarity in the reports of the increase in severity of the present syphilis in India, and the reports of the severity of syphilis among the British troops in Portugal in the early years of this century, as described by Fergusson. One of the reasons suggested by Fergusson was the abuse of mercury. He did not suggest that that was the cause in India, but it might be one of the factors at work to produce a malignant form of the disease. Again malaria deserved consideration. In about thirty per cent. perhaps of cases of syphilis in malarial subjects the disease became malignant. Then again in malarial cachexia mercury required most careful administration. Again, what was meant by malignant syphilis? Some applied the term to secondary ulcerative progressive lesions of a phagedenic character; others to syphilis with lesions of the vital organs; others to the early occurrence of tertiary lesions. But these very different forms might be due to different causes. Malignant syphilis needed definition, and he hoped that subsequent official reports would bring more complete information.

Dr. Shaw-Mackenzie also referred to Fergusson's paper. He thought a key to the malignancy of syphilis might be obtained by watching the attendant circumstances. Thus Fergusson noted that syphilis, although severe among our soldiers, was at the same time mild among the Portuguese. Fergusson referred to the virgin soil presented by our troops. The modification of the severity might be due to natural causes. The virus might be exhausted by age, or successive cultivations in the same soil. Malignancy in malarial cases might be due to the fact that mercury was inefficient in febrile conditions, and thus the disease ran its course uncured. Then syphilis might become epidemic in virulence. The age of the attacked was a factor, young people suffering severely. He referred to the excellent results of supervision in Malta.

Mr. Ward asked, was it really true that syphilis was now more acute in the army? He suggested that the passage of the microbe through the bodies of several Asiatics might increase its virulence. It was a popular idea that syphilis caught from a black person was more severe. Personally he had not found old cases of army syphilis worse to treat than any others. He considered any depressing cause, *e.g.*, malaria or alcoholism, rendered the patient more susceptible to the action of the virus, since it diminished his resisting-power to the microbe. He thought at least one and one-half year's continuous treatment was needed. He approved of Major Lambkin's form of treatment, care being taken not to salivate the patient, but he thought the duration of treatment given was too short. Yet there was a possibility of the mercury injected becoming encapsuled and persisting in the system of the patient, he therefore carrying his supply of mercury about with him. He suggested the use of the *x*-rays to see what became of the mercury.

Col. F. H. Welch denied that the army bred either incontinence or disease. The soldier joined the army

as a healthy recruit, and subsequent disease was a reflex in intensity and frequency of what went on around him in the civil population. We should therefore improve the moral character, and eliminate disease in the civil population. He believed that the Contagious Diseases Acts, despite all their defects, produced a good result, and gave statistics of home-protected stations and India to prove his conclusions. And what were the moral results of these acts? He based his remarks on his own observations and the conclusions of the select committee appointed to inquire into their working. Prostitution was reduced, women reclaimed, juvenile prostitution extirpated, solicitation stopped. Thus, while the physical results were good, the moral results were undoubted.

Lieut.-Col. H. Grier had given fifteen thousand injections of mercury, with no case of salivation and no ill result. The preparation used was mercury ʒ i., lanolin ʒ ii., carbolic oil ʒ iv. He injected 10 minims into the buttock once a week by means of an ordinary syringe.

Staff Surgeon A. E. Weightmann, of the royal navy, believed the Contagious Diseases Acts had done no good at all, and gave figures to prove that disease increased during their application. The examination of women was monstrous. It was declared illegal by the highest authorities in the land. Then ninety-nine women out of one hundred had some form of uterine discharge, syphilitic, gonorrhœal, or innocuous, which it was impossible to differentiate by the examination adopted. Then only one woman in ten or twenty can be got at all. The initial lesion, too, may be readily overlooked, and women not diseased were in danger from the use of instruments. Also the men were led to indulge from a false sense of security. As to the injection treatment, Mr. Hutchinson in his *Archives of Surgery* had mentioned three deaths after injection.

Dr. Maxwell thought that the decrease of syphilis subsequent to the repeal of the Contagious Diseases Acts, and he believed such to be the case, showed that other methods, *e.g.*, moral methods, were still more efficacious. From the percentage of recruits rejected on account of venereal disease he entirely disagreed with Colonel Welch that the civil population were more diseased venereally than the army. Also from the registrar-general's reports syphilis was evidently decreasing in the home population. The Indian army sanitary commission had urged that the Contagious Diseases Acts were inefficient to stop syphilis. He advised voluntary Lock hospitals. Where was the evidence of any national deterioration and degeneration? He saw nothing to suggest that syphilis was increasing.

Surgeon-General O'Dwyer did not find that in Malta the Contagious Diseases Acts had affected gonorrhœa. As to the suggestion for increased lavatory accommodation where men could retire unobserved and wash themselves, such were provided at Aldershot and had failed, as the men would not use them. He suggested some such precaution as had been employed for other reasons in the Curragh (Ireland), *i.e.*, some means by which objectionable persons found in and near camps could be treated as trespassers. In Aldershot the camp thoroughfares were public ways, and no means existed of keeping loose women out of them. He quite disagreed with Dr. Drysdale concerning the frequency of syphilis on the continent. He rather advocated Major Lambkin's injection treatment, as it tended to diminish the hospital population.

---

*Third Day—Friday, August 4th.*

**Gunshot Wound of the Brain.**—Dr. A. Bampton reported a case of bullet wound of the brain. A lad was shot in the head with a toy pistol. The pistol was shown and forcibly illustrated the need of state interference in the sale of firearms, the so-called toy pistols being often more dangerous than real weapons. Dr. Bampton demonstrated that in this case the pistol could be more readily discharged at half-cock than at full-cock. The bullet also would pierce a half-inch deal board. The wound of entry was in the left frontal region. There was no wound of exit, nor any symptom or indication of the locality of the bullet. The *x*-rays were applied with a negative result. In the absence of localization of the bullet it was decided to await events. The patient did well for some time; then vomiting and headache came on. By rest and almost starvation diet the symptoms improved, but when the patient got about again the symptoms recurred. Finally epileptiform convulsions supervened, with symptoms definitely of cerebral abscess. He was trephined by Mr. Victor Horsley nine months after the original injury. An abscess was found in the left frontal lobe and removed entire, the bullet coming away with it embedded in the thick abscess wall. The whole mass, from the appearance of the specimen, was about the size of a hen's egg. The patient made a good recovery and lost all his symptoms. The only adverse factor was the development of a hernia cerebri the size of a walnut at the site of operation. This was treated with astringents and pressure kept up, and after a time it disappeared, a complete cure resulting.

**Excision of the Rectum.**—Mr. Thomas Cawardine read a paper on two cases of excision of the rectum by a new method and its results. The method practised was to put the patient in the position adopted for dissection of the gluteal region in the dissecting-room. This he found an ideal position, so far as the surgeon was concerned, but not so satisfactory for the anæsthetist. The sacrum and coccyx were exposed, and the last two pieces of the sacrum were resected subperiosteally. The bowel was then transfixed longitudinally and divided posteriorly. The growth, now very well displayed, was removed. The peritoneum might or might not be opened. In one of the two cases it was opened and immediately sutured with no ill result. Among other points was the preliminary dieting of the patient with light and liquid food, and if it was thought needful on account of keeping the parts aseptic a preliminary inguinal colotomy might be done. One of the patients operated on was shown. He had good rectal control and sense, and had been able to travel some four or five hours' journey by train to the place of meeting, with the dressing on. A little piece of mucous membrane prolapsed from the anal orifice.

Mr. C. Morton could not see in what way this operation differed from Kraske's operation, and he had a favorable opinion of that operation, both as regards mortality and results.

Mr. Roger Williams also regarded the operation as a modified Kraske.

Mr. Cawardine replied that his points were subperiosteal resection of bone and median transfixion of the bowel.

**Operative Treatment of Goitre.**—Mr. James Berry read a paper and exhibited photographs of seventy-two consecutive cases of goitre treated by operation. He disclaimed any particular merit in his results, but merely brought the cases forward on account of their very considerable number for an English surgeon. Thirty-nine of the operations were enucleations, which he considered as a comparatively simple and safe proceeding. There was no death in these cases. The remainder were extirpations; that is, part of the gland and its enclosing capsule were removed entire. Among the extirpations three deaths occurred; one of them had to be attributed to the anæsthetic. The question when to operate in goitre depended on the amount of trouble the growth was giving, and the ease or diffi-

culty likely to be met with in its removal. In the presence of dyspnœa or dysphagia, or if the surgeon considered dyspnœa likely to supervene, operation was indicated. For mere deformity Mr. Berry would not operate, unless it was causing the patient very great worry, and then he would do only an enucleation, not an extirpation. He related a case in which a lady came to him. No symptoms of compression were present, but he advised operation, as he believed dyspnœa would supervene. Operation was not accepted, and the lady went into the country. One month after, tracheotomy had to be hurriedly performed for severe asphyxial symptoms. As to the anæsthetic, since he had had a death from the anæsthetic, in cases in which dyspnœa was severe he had dispensed with a general anæsthetic, and used cocaine locally. He did not believe there was much pain after the skin and superficial structures were divided, and during the operation the patient was able to give assistance by exclaiming when undue traction was being made on the growth. The most tedious part of the operation was after the growth had been removed; and danger of suffocation being now over, a general anæsthetic might be then given. But when he offered it the patients refused, which he took to be confirmatory of his opinion regarding the small amount of pain. As to incision, the transverse incision was better for the patient, leaving remarkably little scar, and that in the direction of the natural folds of the neck. But for the surgeon it was not so satisfactory. In the last half of his cases he had used, and been satisfied with, the dry aseptic method. He drained for the first twenty-four hours.

Mr. L. A. Bidwell congratulated Mr. Berry on his cases and results. He did not agree with Mr. Berry in his refusing to operate for mere deformity. Enucleation of adenomata in soft parenchymatous glands was a simple and easy procedure. Young, delicate girls often worried very much, and mere worry might induce further symptoms, and in this class he would operate. He operated also for the presence of nervous symptoms which could be traced to absorption of the products of the tumor. He was by no means so hopeful as Mr. Berry about local anæsthesia. In one case in which the patient returned for a second operation, she refused to have it without a general anæsthetic. He took it that patients might be induced to do without an anæsthetic once, but not a second time. He did not approve of the use of the drainage tube. It increased the risk of sepsis. He was surprised at its use.

Mr. Power asked whether Mr. Berry had found any difficulty in respiration during the operation due to division of the infrahyoid muscles.

Mr. Berry, in reply, said that he would enucleate in bad cases of worry, but would not extirpate. He agreed that the use of the drainage tube did somewhat increase the risk of sepsis, but venous hemorrhage was so frequent after these operations that he always drained for twenty-four hours. He had never seen any difficulty in respiration due to division of the infrahyoid muscles. The muscles must never be divided in the same plane as the skin incision, the risk of their non-union being thereby much increased. If they did not unite very considerable and unsightly deformity resulted. The skin should be divided and raised, and the muscles divided some distance away.

**Resection of the Stomach.**—Mr. Charles Morton described a case in which he resected fully three-quarters of the stomach for malignant disease. The portion removed was the three-quarters toward the pylorus, a part of the cardiac end being left and forming the new stomach, which was joined to the cut end of the duodenum by Murphy's button. So far as he knew this was the largest and most extensive removal of the stomach ever done in this country. The patient did well. There was a little leakage after some days along the track of the drainage tube, and he therefore congratulated himself that at the time of operation he had decided to use a drain. He operated under the impression that the case was one of carcinoma, but subsequent examination showed it to be sarcoma. The specimen was exhibited. The patient recovered.

Mr. B. G. A. Moynihan considered pylorectomy for malignant disease unjustifiable, as it was impossible to judge of the extent of the disease, or whether dissemination was present, which in his experience was always the case. He had always in these cases found either affected glands or secondary growth or growths.

Mr. W. G. Spencer did not agree with Mr. Moynihan. He believed in many cases neither glandular enlargement nor secondary growth was present.

Mr. Roger Williams said he had seen in the museum at St. Bartholomew's Hospital a specimen which seemed to him much like the one presented. It was a case of diffuse carcinoma, sometimes called "india-rubber water-bottle" stomach. He asked whether this might not be the same condition.

Mr. L. A. Bidwell up to this year might have agreed with Mr. Moynihan; but this year he had had four cases that were certainly suitable for operation. In them he found neither glandular enlargement nor dissemination. It was largely a matter of luck in the run of the cases. The more extended the series coming under observation the more often would the surgeon meet with suitable cases for operation such as Mr. Morton's. He would, however, have operated in two stages—gastro-enterostomy first, and excision of the affected area afterward.

Mr. Morton replied that certainly if glands or secondary growth in the liver or elsewhere had been present, he should not have operated. He saw no advantage in operating in two stages. He did not think the leakage was due to Murphy's button, as had been suggested by one speaker.

**Operative Treatment of Hæmatemesis.**—Dr. G. E. Armstrong read a paper advocating operation in severe hemorrhage from the stomach. He divided cases of stomach hemorrhage into two groups—small repeated hemorrhages coming probably from capillaries and amenable to medical treatment, and large sudden hemorrhages due to ulceration into arteries and not yielding to ordinary treatment. He related the results of post-mortem examinations in the latter class of cases at the Montreal Infirmary. The arteries were found open, and in some cases admitting a probe. In these cases he advocated operation to secure the bleeding point.

Mr. Spencer congratulated Dr. Armstrong on his paper. He himself had operated on two cases, and found the two ulcers with arteries running across them and exposed in their floors.

*(To be continued.)*

---

**Practical Aseptic Midwifery.**—Dr. Alfred Moore (*Memphis Medical Monthly*, February) concludes the above article as follows: "Do not make an examination without you are clean, and make as few examinations as possible. Do not use the grease pot generally found about the room. Do not have anything about the bed that is not clean. Do not attend a case of labor without you are clean enough to assist in a laparotomy. Do not proceed with the examination until the patient is clean. Respectability is no barrier to infection and disease. Do not use ergot and douche if there are no indications. Do not use more than one ligature on the cord if there is only one fœtus. Do not use any but clean pads to the vulva. Do not fill your satchel with a dirty Kelly pad that has been used in all sorts of cases, but in its place carry antiseptics."

## THE PRACTITIONERS' SOCIETY OF NEW YORK.

*One Hundred and Forty-Eighth Regular Meeting, Held Friday, May 12, 1899.*

W. GILMAN THOMPSON, M.D., PRESIDENT, IN THE CHAIR.

**A Case Twice Operated upon for Gall Stones in the Common Duct.**—DR. CHARLES MCBURNEY reported his case. The patient, S. M——, fifty-four years of age, became ill in November, 1895. His illness began with a sudden chill immediately followed by pain in the epigastrium, back, and neck. He was soon jaundiced; his stools became clay-colored, the urine was dark with bile. Nausea, headache, drowsiness, and intense pruritus were also noted. At the end of a week most of these symptoms disappeared, but the jaundice continued and the patient's general health was much impaired. Numerous mild attacks characterized by the same symptoms followed. The patient lost weight to the extent of thirty pounds. Physical examination revealed a well-defined point of tenderness on deep pressure at a point one inch internal to and a little below the tip of the tenth costal cartilage.

An operation was performed on February 20, 1897. A vertical incision through the rectus muscle near its outer border was made. The gall bladder had so completely atrophied that no trace of it could be found. Exploring the common duct with the fingers, a good-sized calculus could be made out within the duct and situated about one inch from its lower end. The stone could be easily moved upward, but could not be pushed nearer to the duodenal end of the duct. An incision was made in the wall of the duct, and the calculus, about half an inch in diameter, was extracted. The wound in the duct was carefully sutured with catgut in two tiers; a glass tube surrounded with gauze was passed to the bottom of the wound, and most of the wound in the abdominal wall was closed. No untoward symptoms followed, but a rather free discharge of bile soon appeared, which ceased, however, on March 6th, fourteen days after the operation. The patient was dismissed with completely healed wound on April 3d.

This patient regained his weight and remained in perfect health for eighteen months, that is, up to September, 1898. Slight jaundice was then noted and a general impairment of health followed, with great loss in weight. During the following six months four or five acute attacks similar to the initial one in 1895 occurred, and during the whole of this time jaundice was constant. The diagnosis of gall stone obstructing the common duct was again made, and a second operation was performed on April 13th. An incision close beside the old cicatrix was made. Numerous adhesions were met with between the duodenum and the liver. These were disposed of without much difficulty. On exploring the duct with the fingers a calculus could be felt situated quite near the lower end of the duct and entirely covered by the duodenum. It would have been quite impossible to remove this calculus through an incision in the wall of the duct, as the calculus was firmly fixed so low down. A vertical incision was then made in the anterior wall of the descending duodenum. This was held open with retractors, and after some search the lower orifice of the duct was found and a probe passed into it. The calculus was felt about a quarter of an inch from the orifice of the duct. With a finger behind the duodenum the lower opening of the duct was lifted forward into the wound in the duodenal wall; the orifice wall was stretched and partially cut with scissors, and the calculus was readily removed. The wound in the duodenum was then carefully sutured and the whole abdominal wound closed, excepting a small point in the skin wound left open for drainage of blood. At the present time, the speaker said, all bad symptoms had disappeared, and the patient appeared to be once more in excellent health.

DR. JOSEPH D. BRYANT said that Dr. McBurney was to be congratulated upon the successful outcome of the procedure which he had adopted for the removal of the gall stone. The speaker said he had not yet met with a case in which he had found it necessary to resort to that method. In the last case of impacted gall stone which came under his observation, the calculus was located in the common bile duct, about three-quarters of an inch from the duodenal orifice. The case was of particular interest, as the symptoms had persisted for about three years, although not constantly. The last attack was prolonged to such a degree that the patient entered the hospital and asked for surgical relief. The usual incision was made, and a calculus, weighing just one hundred grains at the time of its removal, was taken from the common duct. The stone was quite firmly impacted; so much so that even after making an incision quite large enough for its escape it was pushed out with difficulty. The incision in the duct was then closed, leaving a small opening for the introduction of a small rubber tube, about which some gauze drainage was packed. The wound healed very kindly, bile ceasing to appear after about three weeks. The patient had had no trouble since the operation.

DR. BEVERLEY ROBINSON said that in one case of gall-stone obstruction which had come under his observation he had reason to regret that operative interference was not sooner decided upon, as the patient died before it was undertaken. On the other hand, he knew of cases in which an operation was done without a stone being found, this being due either to an error in diagnosis or to the fact that the stone had made its escape. In one such case, death followed the operation. The speaker asked Dr. McBurney how long, in his opinion, the physician should rely upon medicinal treatment in these cases before invoking the aid of the surgeon.

DR. MCBURNEY, in reply to Dr. Robinson, said there were two classes of cases of bile-stone obstruction, the acute and the chronic. The latter usually came under the surgeon's care after the symptoms had existed for a long time; there was clearly a chronic obstruction of the duct, and the symptoms indicated that there was no particular change going on excepting such as was disadvantageous to the patient. Those cases should be operated on as soon as that conclusion had been reached. Most of the cases which had come under the speaker's observation were of that nature. In one case on which he operated, the condition had lasted eighteen years. The acute cases, in which the obstruction had come on recently, deserved much consideration. In such a case there was always doubt whether the condition was the beginning of a chronic obstruction, or whether the stone was making its way downward and would finally escape. Perhaps the best and safest guide in these cases was the condition of the patient. Frequent attacks of pain indicated efforts on the part of the duct to push the stone along, and if the patient was not made really ill by them, it might be well to wait. If, on the other hand, there was fever, with increasing tenderness, and the patient was really ill, an operation would be advisable. The speaker referred to a case of this kind in which he had been called to operate a few months ago. The patient was a surgeon who had suffered from repeated attacks of biliary colic; these, while they of course interfered with his work and caused intense pain, usually subsided very suddenly. Finally he had an attack which did not subside, and while he was very doubtful that a stone was there, he

desired an operation. Upon the abdomen being opened, nine hundred and sixty stones were found in the gall bladder, not one of which was small enough to pass through the cystic duct and take lodgment in the common duct. Dr. McBurney said he had come to the conclusion that the best way to avoid the difficult gall-stone operations was to operate on those patients who had stones in the gall bladder, with attacks of colic from which they usually recovered without operation. It was much better, he thought, to get rid of the stones which were in the bladder and which furnished the material for these difficult obstructions later on. An operation for the removal of gall stones from the bladder was simple, and patients usually stood it very well.

**A Case of Sarcoma of the Tonsil.**—This was presented by Dr. Bryant. The patient was a man, fifty-eight years old, an accountant by profession, whose mother had died of consumption, and his father of some unknown cause. The patient had nine brothers and sisters. Two of his sisters had died of consumption, one brother of apoplexy; one brother was living and in fair health. The rest of his brothers and sisters died young, of unknown causes. The patient had never had syphilis nor suffered any severe injury. About four years before coming under observation a bone had lodged in his throat for a brief period; it came away without special difficulty and no injurious after-effects were noticed. The man stated that he was perfectly well until January, 1898; then he had a bad cold, terminating in what was regarded as a tonsillitis of the left side; the left tonsil remained enlarged and tender for five weeks, and was then removed at two sittings. He had no special trouble from that time until the following September, when the same tonsil again became enlarged, inflamed, and tender. He came under the care of Dr. Lewis, of this city, who regarded the appearance of the tonsil as suspicious. A specimen was removed and submitted to Dr. Dunham for microscopical examination, with negative result; a second specimen, examined about three months later, was also negative; a third specimen, examined three months after that, gave a similar result. Dr. Bryant said he first saw this patient, through the courtesy of Dr. Lewis, about a week ago. A fourth microscopical examination had just been completed by Dr. Dunham, and this had revealed sarcomatous elements in the growth. One of the cervical glands, located at the bifurcation of the common carotid, was much enlarged; this had enlarged slowly at first, but quite recently had grown rapidly. The patient had taken potassium iodide, in ninety-grain doses, three times daily for two weeks, under the direction of Dr. Lewis, without apparent effect. He had had no pain, and complained chiefly of a sense of stiffness in the throat. There had been no loss of weight, and the patient recently made a business trip to California.

Dr. Robert F. Weir, after examining Dr. Bryant's patient, referred to the comparative rarity of malignant disease of the tonsil. In three cases of this kind on which he had operated, two were followed by a prompt recurrence; in the third, the result was thus far, over one year after the operation, very gratifying. In two of his cases, Dr. Weir said, he divided the jaw-bone, which failed to unite for a long time; in fact, in the successful case referred to there was yet non-union of the jaw. One of the three cases was comparatively easy, and division of the bone was unnecessary. The speaker said that in only one of his cases was the glandular involvement so marked as in the case shown by Dr. Bryant.

Dr. McBurney said that if the case was one of sarcoma, the outlook was very unfavorable on account of the wide area of indurated tissues surrounding the pharyngeal growth. Its removal would necessitate a very extensive operation, including a resection of the jaw, to which Dr. Weir referred. Dr. McBurney said that in those cases in which he had found it necessary to divide the jaw-bone, he had found no difficulty in getting union. The division of the bone was a very disagreeable feature of the operation, but absolutely essential in cases in which an extensive dissection was necessary.

Dr. Peabody inquired whether epithelioma would offer a more favorable prognosis than sarcoma.

Dr. Weir replied that it would, as the infiltration in those cases would be apt to be less extensive.

Dr. Robinson asked if orrhotherapy would be of service.

Dr. Weir said it might be tried in hopeless cases in sarcoma. In epithelioma no benefit was to be expected from this treatment.

Dr. McBurney said he had never seen it prove of any service.

Dr. Weir said he had seen it prove curative in but one instance.

Dr. J. W. Brannan said he recently saw a report made by Dr. Coley regarding orrhotherapy in malignant disease, in which he gave quite a large proportion of recoveries in cases of small spindle-celled sarcoma.

Dr. Edward K. Dunham, who had made the microscopical examinations in the case shown by Dr. Bryant, said the growth seemed to be a round-celled sarcoma, but not of the smallest-celled type. The pieces that he had examined most recently came from two portions of the growth, one a little nodule which seemed to spring from the base of the ulcerated area, and the other from the margin of the ulcer where it was thickened and indurated. The structure was exactly the same in both places. The round-celled tissue was abundantly supplied with small, fine blood-vessels. The speaker said that the specimens of this growth which he had examined previous to these were of an entirely different structure; he did not know from which portion of the growth they had been taken, but they were composed chiefly of mucous glands, with scattered areas of round-cell infiltration and necrosis. In one place there were also three giant cells. He thought at the time that the growth might be a granuloma, possibly of syphilitic origin, but the latest pieces, which were part of the real growth, indicated nothing but sarcoma. Tuberculosis, epithelioma, or any of the granulomata could easily be excluded; also simple inflammatory infiltration.

In connection with his remarks, Dr. Dunham exhibited some microscopic specimens of the pieces of tissue removed.

Dr. Bryant, in reply to a question, said he had no idea where the earlier pieces which had been submitted to the pathologist for examination had been taken from. The patient had but very recently come under his observation. One interesting question which might be raised was, whether the growth was malignant from the outset. If the earlier pieces were removed from the proper situation, then we are bound to assume, from Dr. Dunham's examination, that it was at the commencement non-malignant. An operation in this case, Dr. Bryant said, would necessitate a very extensive dissection. The infiltration extended to the angle of the jaw, involving the soft palate, and extending higher than the edge of the hard palate; moreover, it extended backward and outward, apparently involving the deep tissues of the neck. Its thorough extirpation was practically impossible. It would perhaps be advisable to do a tentative operation removing the glands in the neck, ligaturing the external carotid, and determining then whether a more extensive operation would be advisable.

Dr. W. P. Gibney, in speaking of the importance of the region of the growth from which pieces for microscopic examination should be taken, referred to one

instance, an enormous sarcoma of the thigh, from which he had removed two pieces for the pathologist, cutting into the growth quite deeply for this purpose. The pathologist reported that the growth was a lipoma. It proved to be a sarcoma, however, and was followed by secondary involvement of the left side of the neck.

**An Interesting Case of Membranous Sore Throat.**—Dr. Beverley Robinson reported this case (see page 337).

Dr. J. W. Brannan said he had had some conversation with Dr. Park regarding the case reported by Dr. Robinson, and there was some doubt in Dr. Park's mind as to whether the culture he had taken was a good one; the tube employed was not fresh and the growth was very slight. Dr. Park's own opinion was that the case was one of diphtheria, and that if the culture had been properly taken the Loeffler bacilli would have been found. In contrast to the cases cited by Dr. Janeway, in which the contagion of diphtheria had been carried, Dr. Brannan referred to the fact that during the past four years several hundred students had been taken to the Willard Parker Hospital by himself and other clinical teachers, and in not a single instance, so far as he knew, had the disease been carried outside the hospital. This showed how the spread of infection could be prevented when the proper precautions were taken.

Dr. Peabody said that from the history of the case reported by Dr. Robinson, and also from the good effects of the antitoxin, he was inclined to regard it as one of true diphtheria. The speaker said he had often been disappointed by the result of the culture tests, even when the cultures were carefully made and examined by competent authorities. Frequently the report came back that the case was a "doubtful" one, and a second culture was asked for. Often, if we wished to await the result of a satisfactory culture test, we lost the chief advantage of the antitoxin. Dr. Peabody said he was in favor of giving the antitoxin as soon as the diagnosis was fairly certain. He referred to the case of a governess who was attacked with membranous sore throat. He immediately gave her antitoxin, explaining to her at the same time that he was not certain as to the nature of the affection. A culture was at once taken from her throat, and also from the throats of three children who had been with her that day. The cultures were examined by a well-recognized, competent authority, and the report came back that the culture from the governess was negative, while those from the children, all of whom were well and remained so, showed the Loeffler bacilli in two of the cases; in the third child the result was negative. The children never developed any throat symptoms, and the governess promptly got well, the result we would expect from an ordinary, non-diphtheritic sore throat. When the result of the culture examination was positive, it was of immense value, but when the result was negative, and the indications were that the case was one of true diphtheria, the administration of the antitoxin should not be delayed.

Dr. Peabody expressed the opinion that the unpleasant effects following injection of the serum depended upon individual idiosyncrasy. The speaker said that upon one occasion he had divided a dose of the antitoxin equally among three persons, namely, a boy who was undoubtedly suffering from diphtheria, his mother, and his nurse. The mother and child suffered no ill effects from the injection, but the nurse suffered from skin and joint symptoms. Cases of membranous sore throat were often seen which, while they were not diphtheritic in character, might become very serious. In one such case, which the speaker had seen in company with Dr. Robinson some years ago, œdema of the glottis suddenly developed, necessitating tracheotomy in order to save the patient's life. In that case there were also several alarming attacks of heart failure

**Multiple Sinus Disease following Influenza.**—Dr. Charles Stedman Bull reported this case (see page 336).

**Cases Illustrating the Value of the Microscope in Surgical Diagnosis.**—Dr. Charles McBurney said he thought that he would report these cases to illustrate a practice which was certainly not new to members of the society, but which was often neglected by the profession at large.

Case I.—The patient was a man, forty-nine years old, who first came under observation a few months ago. For about a year previous to that time he had complained of a soreness of the tongue, which was confined to its anterior end, including the tip and sides. Some five weeks before he visited the speaker he first noticed an induration involving the entire tip of the organ. Dr. McBurney found this indurated area very hard; it was clearly defined, about an inch or an inch and a quarter in diameter, and occupying the end of the tongue. It was not very tender; there were no enlarged glands beneath the jaw. The patient was much inconvenienced by the size of the tumor and the unhealthy condition of the surrounding mucous membrane. The appearance of the lesion was suspicious, suggesting carcinoma. A few days later a small yellowish point was observed on the indurated surface, which seemed to indicate pus. An incision was made, giving vent to about fifteen or twenty drops of pus. The incision was enlarged and the wound carefully cleansed; this method of treatment was continued for a couple of weeks without making the slightest impression on the induration. A section of the tissue was then removed and examined by Dr. Hodenpyl, who reported that it was purely inflammatory in character. A second examination was made with a similar result. The induration, however, was so persistent and unyielding that the speaker removed a V-shaped piece of the tongue, and then brought the divided portions together. Complete union was obtained, and when the patient was seen, six weeks later, he was perfectly well, and only a slight amount of induration could be felt along the line of the incision. This case proved the value of the microscope in establishing a positive diagnosis in such doubtful instances. If the growth had been malignant, an operation for its removal would have been both formidable and unsatisfactory; as the growth was bilateral, at least one-half of the tongue would have to be removed, together with a part of the floor of the mouth, and the glands and connective tissue in the submaxillary region. The gross appearance of the condition was very suggestive of carcinoma.

Case II.—The patient was a man, sixty-five years old, who had been carefully examined by his physician, some distance from New York, and told that he was suffering from epithelioma of the mouth. The history of the case dated back to July 16, 1898, when he felt some roughness in the anterior portion of the lower jaw, where he noticed some curious tissue growth. Shortly afterward some teeth in the lower jaw became loosened. There was some pain on the side of the face but not much. The tissue growth increased in size, and the patient, becoming alarmed, consulted a physician, who regarded it as an epithelioma. When Dr. McBurney first examined him, he found the tip of the tongue, the anterior portion of the floor of the mouth, and the entire internal aspect of the lower jaw, together with the gum and surrounding tissue, involved in a curious-looking, partially ulcerated condition, which, while it did not have the appearance or characteristics of epithelioma, did not resemble anything else which he could think of. There was no real induration; the lymphatic glands on each side of the neck were somewhat enlarged. He concluded that if the case was one of epithelioma, its radical removal

would necessitate a very extensive dissection of the tissues, including removal of the symphysis menti and one-half of the tongue. A section of the growth was submitted to Dr. Hodenpyl, and he pronounced it an unusual form of leucoplasia buccalis. At a later examination of the patient, the speaker found that six teeth were rocking in their sockets, and that the gum was infiltrated. This decided him to operate. He therefore made an incision, encircling these loosened teeth, and cutting away all the diseased tissue by a superficial dissection, without interfering with the glands or deeper structures. The patient made a rapid and complete cure. Without the aid of the microscope in this case, the speaker said, he would have felt that he was doing the man a grave injustice in dismissing him without attempting an operation which, on account of his age, might have been followed by serious consequences, and which, in any event, would have left him a cripple for the remainder of his life.

Case III.—The patient was a woman, fifty-three years old, who presented herself with a small tumor in the outer quadrant of the right breast. It was no larger than an ordinary bean; it was not really a part of the breast tissue, and was quite free from the skin. It felt exactly like one of the small fibrous growths we meet with on the surface of the breast. The nipple was not involved. A small piece of the tumor was excised and examined. It turned out to be pure carcinoma. This led the speaker to do an operation of considerable extent, which proved very satisfactory. Without the aid of the microscope in that case, he would probably have been satisfied to remove the tumor through a small incision, although he had seen other cases of true carcinoma of the breast develop in this way.

Case IV.—The patient was a man, seventy-four years old, healthy and vigorous for one of his age, who for about nine months had complained of some uneasy sensations in the rectum. He was also in the habit of passing blood and mucus in his stools several times daily. He apparently had perfect control of the sphincter, and there were no obstructive signs. There was a general sense of discomfort. There was some loss of weight. The patient said that while in London he had consulted three well-known men there, two of them specialists in troubles of the rectum, and after consultation they had agreed in pronouncing the case one of malignant adenoma of the rectum, and had advised colotomy, and for the pain morphine suppositories. When Dr. McBurney examined him, he found, about four inches from the anus, a rather soft tumor, which bled readily, and was attached to the anterior wall of the rectum, just posterior to the prostate. To the finger it felt like a papilloma, rather than an epithelioma; there was no ulceration. He excised a portion of the growth and submitted it to Dr. Hodenpyl, who pronounced it a simple adenoma. This corroborated his own view of the case, and he thereupon extirpated the growth very thoroughly, through a long speculum, the wound which followed its removal behaving very well. Of course, a case of this character, the speaker said, might develop into epithelioma and require further treatment, as was outlined for the patient in London. Still, up to the present time he had escaped the necessity of a colotomy, which would have proved a source of great discomfort and would not in any wise have benefited his condition.

A few years ago Dr. McBurney saw a very similar case in which the growth was also pronounced a malignant adenoma by one of the same gentlemen, who made that diagnosis without the use of the microscope. The growth in that case was an inch and one-half from the anus, and could be exposed with perfect ease. The microscope showed that it was a simple adenoma, which was readily excised, and the patient, four years later, was perfectly well.

**Acute Mania in Graves' Disease.**—Dr. Francis P. Kinnicutt reported a case of this character.

Dr. Charles L. Dana said he had never seen acute mania in Graves' disease excepting as a terminal condition, death being due, apparently, to an overwhelming of the system by the thyroid poison. The thyroid product did not have a direct tendency to produce delirium. Even when administered in toxic doses he had never seen it cause acute psychical excitement, certainly not mania. When that condition did occur in Graves' disease, the subject was probably much predisposed, and the toxæmia must be very severe at the time. On the other hand, there were cases known as menstrual insanities which corresponded very closely to the case reported by Dr. Kinnicutt.

## Therapeutic Hints.

**Uric-Acid Diathesis.—**

| | |
|---|---|
| ℞ Sodii bicarbonatis | gr. xlv. |
| Acidi benzoici | gr. xv. |
| Sodii phosphatis | gr. lxxx. |
| Aq. bullient | ʒ iss. |
| M. Solve et adde : | |
| Aq. cinnamomi | ʒ iij. |

S. Two teaspoonfuls three times daily.

—Golding Bird.

**Glycerin Syrups** as substitutes for sugar-syrups are advocated by Brothers (Transactions New York County Medical Association). Glycerin elixirs may be made with the various alcoholics. The object aimed at is to do away with nauseants and gastric irritants.

**Treatment of Basedow's Disease.**—Dr. Frank Oliphant is credited with the following division of the subject (*Boston Medical and Surgical Journal*, January 12th): (1) The general hygienic treatment, which consists of rest in bed for a certain period of time, and the regulation of the diet, embracing non-stimulating and easily digestible foods; (2) of the drugs, belladonna in large doses does the most good, by restraining the action of the heart, and by decreasing (probably) the secretory activity of the gland. Ung. hydr. iod. externally tends to decrease the size of the goitre; digitalis is effective as a cardiac tonic. Phosphate of sodium, so highly praised by some, has been attended with no results in the author's hands; (3) electricity, so much relied upon formerly, has now given place to more effective means; (4) the author failed to obtain any results from the administration of either the thymus or the thyroid extract; the first one is probably somewhat more efficacious. Pancreatic emulsion, suprarenal gland, and spleen have all been used with varying success. (5) Operative treatment by Kocher consists in ligature of the thyroid arteries; other methods are: removal, by excision, of half or more of the gland, and exothyreopexy—the laying bare and bringing out of the gland, leaving it in this position, the usual result being thrombosis of the veins and shrivelling up of the gland. The most recent operation is that by Jaboulay, which consists in the division of the cervical sympathetic. The mortality in all the operative procedures being rather high—fully twelve per cent.—the tendency is making itself felt to resort to operative interference only after medicinal means have been exhausted and proved futile.

**Diet in Asthma.**—Chronic asthmatics—that is, those in whom the attacks have recurred for some months or years—are frequently the subject of indigestion of food, as shown in the symptoms of weight and discomfort after food, and flatulence. This is sometimes the result of over-drugging. In the cases of

peptic asthma, the regular attacks of the disease occur after a meal, usually the heaviest meal in the day, and are associated with indigestion of food. The regulation of the diet of asthmatic patients is of great importance; meals ought to consist only of digestible food, and that in moderate quantity, no heavy late meals being allowed. Remedies such as alkalies after meals given with the view of correcting the indigestion, combined with a proper diet, give great relief to cases of peptic asthma. Although the asthmatic ought to be careful as regards the food taken, it is wrong treatment to starve such a patient; only harm can come of it, inasmuch as the best chance of the patient recovering is an improvement of his general health, and this cannot occur without a sufficiency of food. It is for this reason, doubtless, that cod-liver oil does so much good in some cases when every remedy seems to have failed. The improvement if the oil can be taken is sometimes very marked, rendering possible the diminution, or even cessation, of the inhalations which the patient considered his sheet-anchor.—SIDNEY MARTIN.

**Neuralgia.—**

℞ Chloral ..... 0.5
Menthol ..... 0.6
Cacao butter ..... 2.0
Spermaceti ..... 1.0

—MAYET.

**Migraine.—**

℞ Methylene blue,
Extr. of nux vomica ..... āā 0.01

—STEINDLER.

**Intolerance for Morphine** indicated by phenomena of collapse is obviated by adding ether to the hypodermatic injection.—FERRAND.

**Lasting Anæsthesia** can be produced by spraying chloride of ethyl over a surface previously moistened with a concentrated watery solution of cocaine. Cocainized chloride of ethyl has been employed for opening abscesses, etc.—BARDET.

**Senile Pruritus.**—Upon the principle that senile pruritus is dependent upon intestinal autointoxication, it is recommended that after purging the patient a milk diet be ordered and an intestinal antiseptic (2 gm. benzo-naphthol daily) be administered. Even in severe and obstinate instances good results have been obtained within twenty-four hours.—PARISOT, *Semaine Méd.*, January 11th.

**Therapeutic Value of Marmorek's Serum.**—(1) In pure streptococcic infections the serum undoubtedly exercises a favorable influence on the course of the disease. (2) In mixed infections the influence of the serum was demonstrable, but it merits further trial as an adjunct to other treatment. (3) Considering the grave character of complications of non-streptococcic nature reported, ordinary rules of therapeutics would demand that in such cases, as with the diphtheria antitoxin, all indicated therapeutic procedures must be employed, as well as the serum. (4) In view of the fact that erysipelas streptococci and phagocytes often exist side by side in the lymph channels, it is fair to assume that the influence of the serum is directly exerted bactericidally on the streptococci and not entirely through stimulation of phagocytic action. (5) The initial dose in all cases should be 20 c.c., to be followed by 10 or 15 c.c., according to the indications, each twenty-four hours.—BAUM, *Medicine*, vol. v., No. 1.

**Treatment of Ankylostomiasis.**—Anæmia, tropical anæmia, or progressive pernicious anæmia, is a disease prevalent in the West India Islands, and is due to the parasite known as ankylostoma duodenale. Some interesting reports have been made by Dr. Galgey, of St. Lucia, demonstrating the usefulness of the drug thymol as a curative agent. He reports that most of the cases are among coolies, but the natives are also very prone to contract the disease. The miserable, dejected, and despondent appearance of the sufferer is characteristic of anæmia. The pale, waxy complexion, the difficulty of breathing, and the slow labored walk, show that the patient is utterly unfit for work. He has dyspnœa on the slightest exertion. At post-mortem the usual pathological signs of anæmia are present, and numbers of the worms can be found in the contents of the intestines if allowed to settle in a basin. The treatment, according to Dr. Galgey, is, after keeping the patient on a milk diet for a day or two, to give a brisk purgative, to be followed next morning by two doses of thymol, gr. xx. each, given at intervals of two hours. If there is no evacuation for some hours after the second dose, an ounce of castor oil is administered. The thymol is given in large capsules.

**Morphine Solution** for use in threatened death, syncope, asphyxia, etc.:

℞ Morphinæ hydrochloratis ..... 0.20 cgm.
Atropinæ sulphat. (neutral) ..... 0.02 "
Aq. dest. bull ..... 10.00 gm.

—FERRAND, *Gazette des Hôpitaux.*

**Artificial Serum** for subcutaneous or intravenous use:

℞ Sodii chloridi ..... 8.00
Sodii saccharat ..... 0.33
Aquæ ..... 1,000 c.c.

This fluid more nearly approaches that of the blood than those in ordinary use, and has been employed with good results.—SCHUCKING, *Deutsche med. Wochenschrift*, No. 19.

**Osteocopic Pains due to Syphilis.—**

℞ Extr. aconiti ..... gr. x.
Pulv. glycyrrhiz ..... ʒ i.
Extr. glycyrrhiz ..... q.s.
M. ft. pil. No. xl. S. One morning and night.

—DEVERGIE.

**Infantile Diarrhœa.—**

℞ Bismuth salicylate ..... gr. xxiv.
Gum arabic ..... ʒ i.
White sugar ..... ʒ iss.
Water ..... enough to make ʒ vi.
M. To be kept on ice. S. One to two teaspoonfuls to be taken three to six times a day.

℞ Mercurous chloride ..... gr. ij.
Zinc sulphocarbolate ..... gr. iij.
Pepsin ..... gr. xxx.
Bismuth subnitrate ..... ʒ ij.
Divide into twelve powders. S. To a child one year old give one powder three times a day.

—MIKHREVICH.

**Vomiting in Children.—**

℞ Potas. bicarb ..... gr. xxv.
Acidi citric ..... gtt. xvij.
Aq. amygdalæ amar ..... ʒ i.
Aquæ ..... ʒ ij.
M. S. Teaspoonful every time vomiting occurs.

—HOLT.

**Hiccough.**—Firm and prolonged depression of the tongue downward and backward.—KOLIPINSKI.

**False Labor Pains.**—As soon as false labor pains are suspected, a four-quart enema should be given at once, and then gr. ½ of morphine hypodermatically. The morphine may be repeated by the mouth in an hour or two if the pain lessens but does not disappear. Nothing stops the pain so rapidly as an enema. Do not think of cathartics. They take too much time, and may increase the irritation.. In some cases it is impos-

sible to stop the colic until after hot drinks, as ginger and peppermint, or inhalations of chloroform, and even hot fomentations and flaxseed-meal poultices, have been used.—T. MITCHELL BRUCE.

**Diarrhœa Mixtures.—**

℞ Tincture catechu ..... 0.6 c.c.
Tincture of opium ..... 0.6 "
Chalk mixture ..... 30 "
Repeat this dose every two hours till relieved.

℞ Compound tincture lavender..... 120 c.c.
Sugar..... 15 gm.
Camphor water.....to make 500 c.c.
Dose: Tablespoonful every two hours.

℞ Tannalbin ..... 1 gm.
Powdered opium..... 0.06 "
Take one such powder every two or three hours until relieved.

This is a very good combination, and one greatly favored. Its action is prompt and highly satisfactory.

℞ Lactic acid..... 10 gm.
Syrup..... 200 "
Water ..... 800 "
Dose: Tablespoonful every two hours (in chronic diarrhœa).

℞ Tincture capsicum..... 4 c.c.
Spirit peppermint..... 8 "
Tincture opium ..... 12 "
Compound tincture catechu,
Tincture kino,
Tincture krameria,
Spirits camphor,
Water.....āā 16 "
Dose. One-half to one teaspoonful.

℞ Aromatic sulphuric acid..... 8 c.c.
Tincture opium ..... 8 "
Water.....to make 30 "
Dose: Teaspoonful in water every four hours.

—*Merck's Reports.*

**Lockjaw.**—Throw the patient into a violent perspiration by raising the bed-clothes over hoops and placing beneath them several deep vessels filled with quicklime slightly moistened and protected from contact with the body's surface.—*London Globe.*

**Appendicitis.**—The local treatment is either the application of an ice-bag over the iliac fossa, or, if this cannot be used, hot compresses. Care should be taken to avoid changing from one to the other, as the change provokes peristaltic action.—ROMME.

**Gastrectasis.**—Dyspepsia and gastrectasis have many symptoms in common, but there are many points of difference. The delayed vomiting, the thirst, and the rapid emaciation in a case supposed to be dyspepsia should excite a suspicion of the existence of a dilated stomach.—WILLIAM MURRELL, *Pacific Medical Journal*, March.

**Proper Food for School Children.**—Mrs. Rorer claims the apple to be the most valuable of fruits. She says: "It has been my observation, after most careful experiments, that both children and adults who eat freely of good, ripe, mellow apples, either raw or baked, and with the skins removed, are free from various forms of indigestion, liver trouble, and constipation; a scraped apple is more easily digested than one partly masticated. The skin of an apple is no more desirable than the outside bran of wheat. The ripe, mellow peach is really the only fruit for children. The banana, in its true home, where it becomes mature before picking, forms an important part of the diet of the inhabitants. Many varieties, however, used there in an uncooked condition, will not bear transportation; consequently those which are sold in our markets are of an inferior variety, picked long before they are ripe or mature, and the ripening of which is almost a premature decay; they are exceedingly difficult of digestion, and children should never be allowed to eat the ordinary banana unless cooked. Baked bananas are very popular. Fried bananas, as well as all other fried foods, are to be condemned."—*Tri-State Medical Journal and Practitioner*, March.

## Correspondence.

### LETTER FROM NATAL.

(From our Special Correspondent.)

CONDITIONS OF MEDICAL PRACTICE IN NATAL—DANGER OF THE PLAGUE—PREVALENT DISEASES.

DURBAN, NATAL, July 20, 1899.

IN this initial letter from Natal the writer may be allowed briefly to remind the readers of the MEDICAL RECORD as to the position, population, and medical service of this British colony.

Natal is on the southeast coast of Africa, lying as to its sea border between the Cape Colony and Portuguese East Africa. The European population is about 55,000; Indian population, imported coolies and their descendants about 60,000, and a native or Kafir population of 550,000. The bulk of the white population is congregated in the towns of Durban, Maritzburg (capital), Newcastle, and Ladysmith. There are in all these towns medical men in private practice independently of government subsidies, while in the more remote country districts the government pays the district surgeon a small annual sum, as a sort of retainer, for which he is expected to do certain work for the government. There is another class of subsidized or contract physicians in the country, and these are known as the Indian Circle surgeons. They are appointed and paid by the immigration board, to medically supervise the health and well-being of the indentured Indians who are mostly engaged in the coast industry of sugar-growing. Before commencing practice a newcomer must submit his diplomas to the Natal Medical Council. After being passed by that body a license to practise is granted, and an annual fee of £5 is levied. Since the medical act of 1897 only those diplomas are passed which would entitle the holder to registration in Great Britain.

As the colony through its port, Durban, is in constant steam communication with India, the chief interest of medical men has been for some time the questions, Will plague be imported here, and if so will it spread among the Indian and native population? This question became so urgent that some three months ago the government stopped the immigration of coolies from India, and further secured from the Indian government the services of one of their plague medical men. This gentleman, Captain Leuman, Indian Medical Service, has just given two very interesting and exhaustive lectures on plague to the medical practitioners of Durban, and as the lecturer has had the experience of ten thousand cases of plague his remarks have the weight of some authority. Dr. Leuman also showed several preparations of the plague bacillus and described the preparations of Haffkine's preventive, which he said was of the greatest service. The profession in Durban now feel quite prepared to diagnose and treat plague.

The diseases we have most to do with here may be said to be enteric fever, dysentery, dengue fever, and influenza. There is no malaria endemic in the colony. Cases are constantly imported from East Coast ports and Mauritius. Among the Indian population cases of leprosy occasionally crop up, while among this class beri-beri is by no means uncommon. Now and

then one hears of a case of Guinea worm. The natives are on the whole a particularly robust race, and one is more rarely asked to prescribe for them than for Europeans and Indians.

Those medical men who belong to the volunteer force of the colony are now taking considerable interest in Transvaal affairs.

## TREATMENT OF PNEUMONIA.

To the Editor of the Medical Record.

Sir: The Medical Record for July 8th contains a note by Dr. E. J. Whitehead on the treatment of pneumonia by inhalations of chloroform. He refers to the suggestion of Dr. A. H. Smith that inhalations of chloroform may be used in pneumonia "to render the exudate inimical to the development of streptococci." In this connection it is interesting to note that chloroform inhalations were first employed in the treatment of pneumonia by Baumgärtner in 1848. In this he was soon followed by Wucherer, Helbing, Werber, and others. Baumgärtner called this the "antiparasitic method" of treatment, and because of its alleged efficacy stated that it might well be considered the "abortive treatment." One of Werber's patients, after recovery from an attack of pneumonia, could not find words adequately to thank his physician for making him feel "so well and strong." Of Helbing's sixty-two patients five died; of Schmidt's seventeen patients one died; of Wucherer's ninety-two patients one died; of Baumgärtner's thirty patients three died. Thus, of two hundred and one cases seven were fatal —a death rate of 3.5 per cent. It is to be understood, however, that other and active measures were employed in the management of the cases. Your correspondent will find this subject freely discussed in Baumgärtner's work, "Lungenentzündung," Stuttgart, 1850. During the past half-century inhalations of chloroform have often been employed in pneumonia, but professional confidence in its usefulness has never been attained.

Inhalations of almost every volatile substance—ethyl iodide, nitrite of amyl, etc.—have been used in this affection, as may be noted by consulting the literature of pneumonia.

Edward F. Wells, M.D.

4571 Lake Avenue, Chicago.

## THE PREVENTION OF TUBERCULOSIS IN ILLINOIS.

To the Editor of the Medical Record.

Sir: Your editorial of the 12th inst. has brought to my attention the fact that in his recent work on "Pulmonary Tuberculosis," Dr. S. A. Knopf makes a statement that in Illinois nothing is done to stop the spread of tuberculosis in either man or beast, and that the board (presumably the State board of health) has never passed any law or resolutions concerning tuberculosis. Dr. Knopf entirely overlooks that in this State there is a most efficient State board of live-stock commissioners which has been in existence for fourteen years.

Not until the discovery of the efficacy of tuberculin as a diagnostic agent did this board deem it wise to undertake steps to eradicate this disease from among domestic animals of the State. Since 1895 this board has conducted tuberculin tests in all cases in which applications from owners of dairy or breeding herds have been received, and has caused to be destroyed all animals that reacted. Every animal destroyed has been examined post mortem, and the reliability of tuberculin as a diagnostic agent, when used in the hands of an expert, has been satisfactorily demonstrated.

During the two years prior to the 31st of last October nearly one thousand dairy cattle were tested, and a fraction of over twelve per cent. of these were found to be affected and were destroyed. Not until the session of the last legislature have any funds been appropriated to be especially applied in dealing with tuberculosis. The general assembly which adjourned in April last made an appropriation of $5,000 per annum with which to make compensation to owners of cattle found by the tuberculin test to be affected with tuberculosis, and since the adjournment of that body in the neighborhood of three thousand dairy and breeding cattle have been tested. The crusade against tuberculosis will be conducted as vigorously in this State in the future as the funds at the disposal of the authorities will permit, and it is hoped that the next legislature will make ample provisions for doing thorough and effective work.

Pursuant to recommendations of the State board of live-stock commissioners of Illinois, Governor Tanner issued his proclamation taking effect July 1, 1899, prohibiting the importation of dairy or breeding cattle into Illinois from all other States and Territories until after the cattle proposed to be imported have been tested with tuberculin by inspectors recognized by the State board of Illinois. The regulations under this proclamation are being strictly enforced, and it only remains for the General Assembly to provide sufficient funds to enable the Illinois board to deal successfully with this disease in Illinois. J. A. Egan, M.D.,

*Secretary Illinois State Board of Health.*

Springfield, August 16, 1899.

## THE HEALTH OF TROOPS IN THE TROPICS.

To the Editor of the Medical Record.

Sir: In the vast majority of circumstances, the writer believes the physician should abstain from mixing in politics; but when these politics affect the health of the community in which he lives, he may then with propriety actively interfere to the end that these abuses may be stopped and the health of the people preserved. What is true of a community is, in a far greater and wider sense, applicable to the nation; and when an administration, through ignorance of hygienic and climatic laws, attempts to carry out a policy which involves great sacrifice of human life and health, who is there but the medical profession to come forward and warn these political dictators of the dire consequences of their actions?

The conditions prevailing in the American military forces in the Philippines to-day could have been foretold by any intelligently educated medical man in the country, years before the Spanish-American war was even thought of. The primal conditions necessary to the health, nay even to the life of every Caucasian attempting to live in those hotbeds of disease are: thorough housing; careful attention to diet; the practice of working only in the early hours of the morning and the late hours of the afternoon; the midday siesta; and, finally, fleeing altogether from the islands at the beginning of the rainy season, not to return until its close. These are impossibilities in a military campaign, each and every such precaution being neglected—hence an awful and needless sacrifice of life among our soldiers.

Is it not the duty of the medical profession carefully and clearly to set the facts before the officials who are framing our Eastern policy?

The general commanding the Philippine army has

absolutely forbidden the cabling of any hospital reports which show the deplorable results of attempting the impossible. But when well-authenticated facts come to us from other and reliable sources, is it not the solemn duty of every physician in these United States to see to it that the representative of his community in Congress is fully informed of the true condition of affairs, that he may vote and speak intelligently, and perhaps put a stop to the throwing away of the health, and too often of the actual lives, of our young men? Apathy toward an all-absorbing question of public weal is not a characteristic of the average medical practitioner, nor is he a slave of petty partisan considerations, and there certainly has never been a time in the history of our country when the need of sound medical advice has been more pressing. It would be superfluous here to recount the many needful reforms based solely upon medical common sense, but the writer dares to hope that these few words may perhaps serve to direct the attention of his fellows to the well-deserving and important subject, and thereby result in mitigating the crying evils which now exist.

Dixi Crosby, M.D.

Newport, R. I., August 10, 1899.

## Medical Items.

**Clay Dressings.**—Students of medical history know how great value was attributed by Galen and others to Lemnian earth, "terra sigillata," as an absorbent. Dr. Stumpf having noticed the remarkable preservation of a dead body embedded in clay, and considering this due to the antiseptic and absorbent properties of the earth, determined to use the latter in the treatment of suppurating wounds and ulcers. He first sterilizes the clay by heat and then powders it over the wound, covering the whole with a gauze compress. "Under the dressing, which it is often unnecessary to renew, wounds and ulcers rapidly cleanse and cicatrize." Dr. Melissinos, of Gaute, confirms this by the history of a vine-dresser who on the advice of his companions dressed a severe wound penetrating the knee-joint with clay, and though not otherwise attended to for fifteen hours the wound healed by first intention and the joint remained intact.—*Medical Magazine.*

**Lawson Tait and His Delusions.**—A physician writing to an English paper on this subject expresses himself as follows: "A very high priest of scrupulous asepsis, by some strange mental obliquity Tait never could—or would—see that his method was really based upon the same principles as the antisepsis of Lister, and hence to the day of his death fiercely denounced and ridiculed the entire germ theory of wound infection. Thus we have the curious double contradiction of a paladin of modern surgery attacking the position on which his own success was based, and of the antiseptic method being helped to the higher and safer ground of its bitterest opponent. The germ being absurd, its principal experimental proof, animal inoculations, must be ridiculous also, and his next attack was directed against vivisection on the ground that it was misleading and productive of no useful result. These two antipathies so grew upon him that he directed that the inscription upon his tombstone should be the statement that he had devoted his life to warning the medical profession against the 'delusion' of vivisection. Singular in death as in life, he also ordered that, his body having been cremated, the urn containing his ashes should be placed in a cave in the grounds of his house at Llandudus, and that no gathering or ceremonial of any sort should be permitted at his interment. Strange that a man should prefer to be remembered by his weaknesses instead of by his masterpiece, and should order to be graven on his tombstone that for which he needs forgiveness and oblivion. His work will long outlast his tombstone, and his cutting reply to the German surgeon who asked the secret of his success, 'I keep my finger-nails clean,' accompanied as it was by a glance at the mourning-tipped fingers of his questioner, will long live as the aseptic theory in a nutshell."

**Notification of Contagious Diseases.**—Dr. F. Willoughby, the health officer for Eastbourne, England, thus summarizes the arguments for and against the notification of diarrhœa, measles, and whooping-cough:

*Pro:* (1) The large total mortality from the diseases and the still larger suffering, and the desire to do "something" to prevent it; (2) the possibility that by circulars and otherwise sanitary authorities could teach parents that many of the deaths from measles are preventable, and medical men would be oftener called in; (3) the attention of the sanitary authorities would be drawn to insanitary houses.

*Con:* (1) The cost; (2) the fact that medical men are often not called in, and the parents being lay could not reasonably be compelled to diagnose cases, or be fined if they did not; (3) the unnoticed mild cases which spread infection; (4) the fact that the early symptoms are those of a cold, and thus the case is often missed; (5) opinions are divided as to its having been a success anywhere that it has been tried.—*Sanitary Record.*

**Tuberculosis Among Animals.**—Nearly one-fourth of the deaths among the animals at the British Zoölogical Gardens last winter were due to tuberculosis. This is nearly double the human average, and confirms the rapidly growing belief that the disease is emphatically one of confinement and overcrowding, for the society's superb menagerie is shockingly cramped for room. It is no credit to the public spirit and civic pride of London that this state of affairs should have been so long allowed to continue. For five years past the size of the gardens has limited the size of the collection. Now in New York the civic body has presented its Zoölogical Society with a park of two hundred and sixty-five acres, has paid one-third of the cost of its equipment, and agreed to bear half the expenses of its maintenance. No official body of any sort in London contributes one penny toward the support of our own gardens, and behold a death rate of over forty per cent. per annum which the society is powerless to prevent. The differences in the distribution of the disease between the various classes of animals at the Zoo are marked. Reptiles of all sorts are almost exempt, probably because the tubercle bacillus cannot live at the low temperature of their bodies, although two or three suspicious cases were found in tortoises and pythons. Animals suffer nearly fifty per cent. more severely than birds. But the most striking difference is that between the meat-eaters and vegetable feeders. Among vegetarians (monkeys, antelopes, deer, and kangaroos) it causes twenty-six per cent. of all deaths; among meat-eaters (lions, wolves, small cats, civets) barely three per cent. Among grain-eating birds (pheasants, pea-fowl, grouse, ostriches) tubercle is responsible for thirty per cent. of all deaths. Among flesh-eaters (eagles, vultures, owls, crows) eleven per cent. Comment is superfluous. An open-air life and a meat diet are clearly the best protection against consumption.—*English Outlook.*

**Brooms as Germ Breeders.**—Bacteriologists devote themselves to the detection, isolation, and destruction of bacteria, and, strange to say, they do not appear to

have given much attention to the danger that lurks in the ordinary articles of household use. For example, the common house-broom is both the habitation and breeding-place for whole colonies of bacteria, and cases of disease have been traced to this apparently inoffensive article. At Königsberg a course in bacteriology is being given by a physician, in which he maintains that the strictest sanitary and hygienic condition in things pertaining to the house should be inculcated; and in this country, in the Boston Cooking-School, and doubtless elsewhere, there are many lectures given on bacteriology. The refrigerator is one of the danger spots, for bacteriologists tell us that the minutest organisms may thrive even in melted ice, and putrefactive bacteria once gaining access to the household refrigerator will breed and contaminate butter, milk, meat, and other foods kept therein. Cupboards and closets also afford an excellent breeding-place for the ever-present microbe, and housekeepers will do well to look to such articles as refrigerators, brooms, dusters, etc.—*The Scientific American.*

**What's in a Name?**—The scare in Paris at the report that the plague had appeared on French soil suggests that there may be much virtue or the converse in a name. If the disease was not known as the "plague" or its equivalent in all languages, people would not be nearly so frightened by it as they are now. In the good old days before sanitation became a science, cities used to fester on growing accumulations of their own filth till a pestilence came and swept off ninety per cent. of the populace. Then the wretched remainder sneaked off and started a new city on a clean site; and from a high tower near Delhi you can see the ruins of a dozen plague-sacked Delhis. What wonder, then, that the plague became a name of terror. Now, however, epidemics of cholera or typhoid fever, dengue or yellow fever, malaria or diphtheria may be more deadly than "the plague," and if all the world conspired to taboo the name and call it simply "bubonic fever" or bubonia, even the French might remain calm—Mark Twain has described French calm—in the face of it.—*To-Day.*

**Health Reports.**—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended August 25, 1899:

SMALLPOX—UNITED STATES.

| | | Cases. | Deaths. |
|---|---|---|---|
| Florida, Jacksonville | August 12th to 19th | 1 | |
| Louisiana, New Orleans | August 12th to 19th | 1 | |

**Shoes for British Soldiers.**—Military authorities in England, it is said, have at last decided to make a change in the footwear of the British infantry soldier. The army shoe is constructed to wear well, but little attention is paid to comfort or convenience. This is to be altered, and a shoe that combines comfort with endurance is to be supplied. As Mulvaney remarks, "A soldier in war is no better than his feet."

## Books Received.

### REFLEX IRRITATION, WITH SPECIAL REFERENCE TO EYE STRAIN, A FACTOR IN NERVOUS AND MENTAL DISEASE.[1]

BY C. A. DREW, M.D.,

MEDICAL DIRECTOR, STATE ASYLUM FOR INSANE CRIMINALS, BRIDGEWATER, MASS.

WHILE the attention of this association is so largely interested in the creditable progress of neural pathology, and the forces of physiological psychology are chasing metaphysical shadows, and every man's thought is upon auto-toxicants, it may be rash to hope to hold your attention for an old theme—some of you will think the worn-out theme—of reflex irritation. And yet, while we conceive of every vital organ as sending neural messages almost constantly to the cerebro-spinal axis, most of which never rise above the threshold of that ill-defined entity called consciousness, we must admit that there may be problems along old lines, whose solution would add to the comfort and possibly hasten the recovery of patients under our care.

Reflex irritation, in the sense I wish to discuss it, means that limited or widespread exhaustion of cortical nerve centres because of nerve currents increased in force or duration from peripheral organs, malformed, undeveloped, or the seat of pathological processes. It includes such molecular and chemical changes as may take place in the conducting nerve fibres for want of physiological rest. It is concerned with the loss of potential energy and the nervous disturbance which an occluded naris, a decayed tooth, or hemorrhoidal swelling may cause. It may, by checking a normal visceral secretion, so interfere with digestion as to favor the formation of those toxins in the alimentary tract, that are charged with so important a rôle in the causation of mental disease. It is not my purpose to attempt to treat this broad question exhaustively. If a thought offered or conclusion reached excites sufficient interest and reaction in the minds of members of this association to call forth a free discussion, the best result hoped for will have been attained. The influence of diseased, malformed, or undeveloped pelvic organs on the mental health of women has been so exhaustively discussed by this association that I shall refer to this only in the most general way.

The central purpose of this paper is to inquire particularly into the importance and *modus operandi* of eye strain as a source of nervous irritation, pain, and wasted energy. I deem it of the greatest importance to consider this question from a dispassionate and non-partisan standpoint. For if there is anything well calculated to bury germs of truth too deep for a resurrection, to discredit well-fortified theories, and bring excellent therapeutic measures into disrepute, it is their intemperate advocacy by those ultra-specialists who, in the language of Dr. Peterson, are prone to "apotheosize the eye, the nose, the uterus, or any single viscus, and make it the divinity to which all other organs must kneel."

I fear it is true that there has been some intemperate discussion of the subject-matter of this paper. I know able men equally experienced who hold and defend opinions which seem diametrically opposed. In considering the differences of our professional brothers we may feel that their knowledge must be very inexact, else their opinions would not be so opposed; but when we forget the "mote in our brother's eye" and remember how often two members of our own association reach opposite conclusions from the same evidence, when called to testify, as experts, in a case at law, our pride may be humbled and we be moved to believe that the human mind tends to belligerency toward the children of other brains, "even as sparks fly upward." A well-known author has declared that even the axioms of geometry would be disputed if men's passions were concerned with them. And so it seems.

I presume it would not be putting it too strong to say that there are many members of this association whose comfort and peace of mind would be seriously impaired by being deprived, for a day, of the glasses they habitually wear. One would simply be unable to recognize his friend across the street; another would suffer from severe headache; another would be nauseated; another, besides headache and nausea, would suffer a degree of mental confusion. Why should these things be? It would better meet the requirements of science first to prove our postulate, but limit of time forbids. Those who have personally had to contend with a hypermetropic astigmatism with corneal meridians of greatest refraction oblique and not parallel will readily grant our postulate. If one who doubts desires to be convinced, I would ask him to wear his neighbor's glasses made to correct an astigmatism of one diopter or more, for only one hour. This will produce an artificial astigmatism in his own eyes which all the forces of the motor oculi and ciliary muscle will, involuntarily, try to overcome.

I mention oblique hypermetropic astigmatism with non-parallel axes, because this is the condition which usually causes greatest eye strain. It might be interesting to consider the reasons why one form of ametropia, such as simple myopia, or myopic astigmatism with axes horizontal, should cause no eye strain, but time again forbids.

The anatomical and physiological factors in these problems are varied and interesting. The function of accommodating and adjusting the eyes in the act of vision, so constantly being performed during our working hours, if we think of it, is exceedingly complex. The ciliary and internal recti muscles being innervated by the same nerve, convergence is so intimately related to the function of accommodation that it is exceedingly apt to embarrass, as it were, the motor oculi, if the ciliary muscle and adductors need different degrees of innervation. This relation will explain why one with relatively weak adductors will appear myopic. He holds his book so near, not because the refractive condition demands it, but that the feeble internal recti may receive sufficient innervation

[1] Read before the American Medico-Psychological Association, New York City, May, 1899.

to hold the eyes properly convergent, he voluntarily increases the load the ciliary muscle has to bear.

The relative strength of the internal and external recti will guide the physician in determining whether or not to prescribe glasses for a hyperopic patient to wear constantly. It is a fact of common knowledge that the majority of children are hyperopic, or far-sighted. This state is so common that some authorities claim the hyperopic eye to be the normal eye. It is not uncommon for this far-sighted eye of childhood to be associated with "esotropia" or internal squint; which, if moderate in degree, almost always yields to the constant wearing of convex lenses, which correct a large part of the hyperopia. The explanation is simple. The adductors had been over-stimulated because it seemed impossible for the motor oculi nucleus to satisfy the excessive demand of the overworked ciliary muscle without giving more than the needed innervation to the internal recti. With the common innervation of the ciliary and internal recti muscles in mind, we can readily conceive of the mental mechanism distressed by conflicting signals if the eye is so hyperopic as to need excessive ciliary innervation in order to focus parallel rays perfectly, while the external recti are so weak relatively that the slightest stimulation of their antagonists, the adductors, causes more than the required convergence. This quite common condition when of high degree constitutes convergent strabismus or the "esotropia" of recent writers, while if the condition be of low degree it constitutes the dynamic strabismus of older authors, and the "esophoria" of Dr. Stevens. We cannot follow further the correlation of ametropia and the different forms of heterophoria, and it would take us to the realm of speculation to inquire how much influence abnormal nerve currents to the motor-oculi nucleus would exert on adjacent nuclei of other important nerves whose deep origin are also in the floor of the fourth ventricle.

Organic palsies and visual defects from organic causes are not within the province of this paper. Indeed, partial or total blindness, or palsy of ocular muscles, is not, as a rule, a source of eye strain. Anatomical defects, acquired or congenital, so gross as to be beyond the power of the visual mechanism to correct by a supreme effort, will not produce eye strain. It is not the cross-eyed man nor the near-sighted man who suffers from this cause; nor is it he whose astigmatism is so great that no effort of the ciliary muscles can compensate for the unequal curvature of different meridians of the cornea. Rather it is he whose eyes can be kept in line and whose ciliary muscle can neutralize anatomical imperfections of the cornea by excessive calls on the nuclei of the fourth ventricle and the cortical motor area of the cerebrum. If it be true, as some authorities allege, that the unstable and highly impressionable nervous organism is marked anatomically by a nerve-cell nucleus small in proportion to its protoplasmic body, then I would say that the relative smallness of the individual's nerve-cell nucleus will determine the degree of general nervous disturbance from peripheral irritation of any kind.

In other days it may have been necessary for the asylum physician to limit his professional studies to the abnormal manifestations of the mind, and his therapeutics to the drugs of the pharmacopœia and the more important disciplinary and hygienic measures which are of as clearly recognized value to-day. It is probable that the public and the general practitioner still regard physicians who care for the insane as specialists in the usual narrow sense of that term. If the general practitioner knew how large a part of our time has been given to the study and treatment of somatic diseases he would realize that there is not a theory or fact related to the prevention or cure of disease, in which we do not have, with him, a common interest.

I am glad to be able to assert, in the language of the day, that history proves this association to have been from the beginning devoted to the theory of "expansion." Times have changed somewhat. The exigences of days past demanded so much of those devoted men, who, one by one, are rapidly falling from the ranks, that the world and the general profession do not know how much their busy lives wrought for medical progress. Our duty to ourselves and to those whose aims were high, when assistant physicians were few and internes unknown, demands that we be loyal to that principle. You will grant it a truism, that whatever science has to offer for the relief of those who are sane should be offered freely and "without price," to those who are insane, if they be indigent. It is pleasing to note that in the progress of evolution and expansion we have absorbed and are utilizing many of the therapeutic measures once adequately employed only by specialists outside our own ranks. It would be exceptional now for a woman patient to come and go from one of our hospitals without a careful gynæcological examination, and this, we agree, is to the credit of our hospitals. The fascinations of pelvic surgery are not likely to lead us into the error of extremes, because the responsibility and veto power are usually held by one whose function as consultant and general manager does not tend to encourage the hobby mind habit. Hydrotherapeutics is fast gaining a deservedly high place in our esteem and claiming a corresponding portion of our time. The routine examination of blood and sputum, and the necessary preparation for the rôle of instructor in the training-school, have added not a little to "the white man's burden." But these are legitimate fruits of our policy of expansion of which I have yet to hear a member of this association complain.

Most modern psychologists agree that every thought or emotion has its bodily equivalent, whether manifested as a contraction or dilatation of the pupils and blood-vessels, the quickened pulse, the changed gastric secretion, the modified respiration, the clenched fist, the moist eyes, the pleased smile, or in a powerful impulse to some voluntary action. I will not here argue the question whether one's face blanches and his knees weaken because he is frightened, or he is frightened because of the bodily changes of which the blanched face, the weak knees, and the changed heart rhythm are but an index. It is an interesting question, and the evidence is not all on one side. It also bears on the relation of mental states as influenced by abnormal conditions of remote organs. Dr. Maudsley writes: "Observe how fear strikes the heart and what anxious fear and apprehension accompanies some afflictions of the heart. . . . The internal organs are plainly not the agent of their special function only, but, by reason of their intimate sympathy of function, they are the essential constituents of our mental life." Professor James holds strongly that those states of mind recognized as the coarser emotions, such as joy, sorrow, anger, hope, and fear, upon which our general health, in turn, so largely depends, are directly consequent to bodily changes. In his own language: "Our whole cubic capacity is sensibly alive, and each morsel of it contributes its pulsation of feeling, dim or sharp, pleasant, painful, or dubious, to that sense of personality which every one of us unfailingly carries with him." Again he writes: "What kind of an emotion of fear would be left if the feeling neither of quickened heart-beat nor of shallow breathing, neither of trembling lips nor of weakened limbs, neither of goose-flesh nor of visceral stirrings, were present, it is quite impossible for me to think."

Whether we believe that the recognition by the cerebral cortex of those material changes in our bodily states is the essence of those mental states we call emotions, or hold to the more commonly accepted theory that these bodily changes are characteristic sequences to certain mental states, we must admit their intimate relation. And with this acknowledged truth of physiology before his mind, who will declare the states of mind to be conditioned by the brain alone, or say he has fully investigated the sources of a mind diseased who has not satisfied himself of the healthy function of every physical organism?

Little direct evidence has been offered in this paper that "difficulties of accommodating and adjusting the eyes in the act of vision are a potent source of nervous disturbance." If the writings of Stevens, Ranney, Amidon, Mittendorf, Webster, Standish, Woodward, Savage, Wilder, Gradle, Ellis, and others have not convinced you, I could hardly hope to succeed. "If they hear not Moses and the prophets, neither will they be persuaded though one rose from the dead."

I hope I shall not be misunderstood; and if I may quote from a former paper: "I would deprecate as much as any one the dominance of any hobby in a hospital for the insane. And while I plead the case of ophthalmology I would not exalt it at the expense of any other line of medical work. If one sees only eye strain and fails to inquire why those cheeks are flushed and that breathing quickened; why those lips are blue and those ankles œdematous; if he looks for evidence of nephritis in the retina alone, and neglects to chemically and microscopically examine the urine; if he forgot the significance of the abolished or exaggerated patellar reflex, and knows not how to interpret the presence of spasm or palsy—though he knows the relation of optic atrophy to all the morbid conditions of the cerebro-spinal system, it will profit little. And if he were so engrossed that he could not stop to cheer the depressed or attempt to change the current of morbid thought from self to hopeful subjects, then his special work would add but little value to his service."

Most of us have ideals which seem more or less beyond our reach; but I am pleased to note that progress along the lines of evolution has brought us nearer and nearer to the methods of the best general hospitals; and I trust the time will soon come when a hospital for the insane without an ophthalmological outfit, and one member of the house staff, at least, familiar with its use, will be as rare as a general hospital without a department devoted to the organs of special sense. The readiness with which older members have reorganized their forces to meet new conditions and added responsibilities ought not to be overlooked, and it would be but a step further along the path of evolution to have every so-called specialty represented by a member of our medical staff—not necessarily to do the more difficult operations in abdominal, pelvic, or ophthalmic surgery, unless the experience had amply qualified, but that every patient might be intelligently and thoroughly examined as a matter of routine. It is the good fortune of many institutions to be located near large cities, where a consulting-board ever available, including able men of all the different specialties, is a possibility. More hospitals for the insane are so located that the whole medical field must be cultivated by the resident staff, if at all. Fortunately the daily staff consultation, introduced into Massachusetts, I think, by Dr. Cowles, helps greatly in the judicious division of labor and permits of developing lines of scientific work impracticable under earlier conditions.

It is necessary for every physician who cares for the insane to be a general practitioner, but it is possible so to organize and educate our staff that each assistant physician may aspire to all the advanced knowledge, in a limited field, popularly supposed to belong to that favored genus, the specialist, alone. Conservatism may save us from the error of those who ride hobbies, but inertia is often counted for conservatism, and it is better to follow a false trail occasionally than not to search for truth at all. I plead not for the acceptance of the theories of any specialist or set of specialists, but rather for the broad application of that ancient admonition: "Prove all things; hold fast that which is good."

## SCARLET FEVER REPRODUCED BY INOCULATION; SOME IMPORTANT POINTS DEDUCED THEREFROM.[1]

By JOSEPH WILLIAM STICKLER, M.S., M.D.,

ORANGE, N. J.

The inoculations were made with a hypodermic syringe. The point of the needle was introduced into the skin, never through it into the subcutaneous connective tissue. Mucus obtained from the throat and buccal cavity (soon after the characteristic eruption appeared) of a patient who had a mild attack of scarlet fever, was the material used for the inoculations. Prior to use it was treated with carbolic acid, according to the suggestion of Chamberland and Roux, the addition of about $\frac{1}{600}$ part of the acid being made.

The virus used in the inoculations produced no other than a slight local effect when injected into white rabbits and guinea-pigs.

Case I.—Louise B——, aged thirteen years. Physical condition perfect before inoculation. Inoculation was made in the arm December 13, at 3 P.M.

December 14th, 9 A.M.: Pain in bowels and diarrhœa. Both ceased in the afternoon, but the patient vomited once. During the evening the characteristic eruption made its appearance on the surface of the body. The skin at the point of puncture was red. Skin hot and dry.

December 15th: Headache; throat sore; the tongue presented the characteristic strawberry appearance. The general eruption was well marked.

December 16th: Throat red, but not sore. The patient slept well during the night and feels well. Appetite good; rash faint; temperature, 98 F.

December 17th: The patient says she feels perfectly well. Rash very faint on body, but pronounced at point of inoculation.

December 18th: General condition good; general eruption gone; local eruption still manifest; temperature, 98.5 F.

December 20th: Well. Temperature, 98.5 F. There was desquamation about the puncture.

December 23d: The throat was somewhat sore again; temperature, 102.5° F. There was general desquamation. The patient made a rapid and complete recovery.

Case II.—John B——, aged eleven years. The patient did not feel as well as usual before the inoculation, but did not specify any particular trouble. Temperature before inoculation, 101.2° F., at 3 P.M.

December 13th: Injected the prepared mucus into

[1] The manuscript of this article was found among the late Dr. Stickler's papers. He had added a note stating that the inoculations were made to prove that a protective virus had been discovered, but when he found that in each instance genuine scarlet fever was developed, with its possible complications, he desisted and turned his attention to another method of protecting the human system against the contagium of this much-dreaded disease. However, the manifest importance of some facts developed by these investigations led the author to prepare them for publication, as he believed they would be of great practical value in the management of all scarlatinal patients.

the skin of the arm. At midnight the patient vomited and had diarrhœa, also sore throat and headache.

December 14th: The patient was sick all day. The arm was red, but there was no general eruption.

December 15th: Temperature, 101.2° F. General eruption, but the patient does not complain of sore throat. There was strawberry tongue, and the visible portion of the throat was redder than normal.

December 16th: Rash still visible; temperature, 99.8° F. He says he feels well.

December 17th: General eruption faint. The eruption about the puncture was most marked. Temperature, 98.8° F. The patient feels well.

December 18th: The patient feels perfectly well. Temperature, 99° F.

December 20th: Temperature, 98.5° F. He feels well. There was desquamation about the inoculation.

December 23d: There was slight general desquamation. He feels well.

This patient made a rapid and complete recovery.

Case III.—Andrew B——, aged six years; inoculated at 3 P.M. December 13th.

December 14th: There was pain in the stomach early in the morning. He vomited in the afternoon. There was slight diarrhœa. The arm was red around the point of injection.

December 15th: The general eruption was well marked; throat sore and strawberry tongue; lymphatics enlarged.

December 16th: No sore throat. He feels quite well. The general eruption was visible, but faint. The local eruption (eruption about puncture) was intense. Temperature, 99.8° F.

December 17th: Temperature, 98.8° F. The patient feels perfectly well.

December 18th: There was eruption about the point of inoculation, but the general eruption was gone. Temperature, 98.5° F.

December 23d: There was general slight desquamation. The patient feels quite well.

Case IV.—Edward B——, aged eight years; inoculated 3 P.M. December 13, 1889. His condition was normal at the time of inoculation. He vomited during the evening.

December 14th, 7 A.M.: He had diarrhœa. During the afternoon there was redness about the point of inoculation. There was no sore throat.

December 15th: When seen early in the morning, general typical eruption was discovered. The throat and tongue were characteristic in appearance.

December 16th: The eruption about the inoculation was intense. The general eruption was well marked. He says his throat is not sore. There was no headache. Temperature, 101° F.

December 17th: Temperature, 98.8° F. He feels well in every respect.

December 18th: He feels perfectly well. Temperature, 98.5° F.

December 23d: There is still a very slight general desquamation.

Case V.—Peter B——, aged four years; inoculated 3 P.M. December 13th. He was well at the time of inoculation.

December 14th: When he arose from bed about 6 A.M. he had slight diarrhœa, vomiting, and sore throat. Later in the day he had the characteristic eruption on his chest.

December 15th: The general eruption was well marked. The tongue and throat were characteristic. No headache.

December 16th: He does not complain of sore throat. The eruption is well marked all over the body. There is a rash about the point of inoculation, very intense. He feels quite well.

December 17th: The patient feels quite well.

December 18th: No change.

December 23d: There was general desquamation. The urine contained a small quantity of albumin. He had pain in the left ear.

December 24th: Albuminuria was more pronounced.

This patient had a sharp attack of scarlatinal nephritis, from which he ultimately entirely recovered.

Case VI.—Conrad K——, aged four years. He is perfectly well. He was inoculated on December 19th at 11:50 A.M. in the left forearm. At midnight of the same day he had fever (mother's statement), headache, and nausea.

December 20th: Early in the morning general eruption was found, with strawberry tongue and temperature 101.8° F.

December 21st: Temperature, 100.4° F. He does not complain of sore throat. The general eruption is well out. The appetite is fair and he feels well.

December 25th: The temperature is normal, and he has experienced no untoward symptoms since December 21st.

General desquamation followed, and the patient made a good recovery without complications.

Case VII.—John O'Brien, aged two years and one month; normal in all respects except where otherwise stated.

December 21st: Inoculation at 1:30 P.M. Temperature at 2:45 P.M., 100.8° F.; pulse, 144; at 7 P.M., pulse, 148. He was restless through the night.

December 22d: I was unable as a rule to get the pulse on account of the child's struggles. At 9 A.M.: temperature, 101° F.; pulse, 140. At 7 P.M., temperature, 101.8° F. The rash was faint over sternal region. He is lively and appetite good. There were swelling and redness around the point of inoculation. The throat, tonsils, and uvula were a little swollen and decidedly red. The tongue was uniformly coated and light gray in color.

December 23d, 9:30 A.M.: Temperature, 99.8° F. The throat was normal. There is a faint rash on the chest, abdomen, and thigh. 6 P.M.: Temperature, 101.8° F.

December 24th, morning: Temperature, 99.8° F. The rash and throat are unchanged. The point of inoculation is small and somewhat red. Afternoon: Temperature, 100.2° F.

December 25th, morning: Temperature, 98.8° F. The inoculation point is beginning to enlarge. Afternoon: Temperature, 97.4° F.

December 26th, morning: Temperature, 99.6° F. The inoculation point is much enlarged. The rash is more brilliant than before. Afternoon: Temperature, 100° F.

December 27th, morning: Temperature, 99.6° F. The abscess at the point of inoculation broke. Afternoon: Temperature, 99.4° F.

December 28th, morning: Temperature, 99.6° F. The abscess at the point of inoculation is still discharging. The rash is faintly visible. Afternoon: Temperature, 99.8° F.

December 29th, morning: Temperature, 97.4° F. The abscess is discharging. Desquamation has begun around the inoculation.

December 30th, morning: Temperature, 98.2° F. There is desquamation on the lower part of the trunk in fine scales. The rash has faded. Afternoon: Temperature, 99° F.

December 31st, morning: Temperature, 99° F. He was restless during the night and thirsty. The abscess continued to discharge slightly till January 13th.

Case VIII.—Fritz V——, aged eight and one-half months; condition normal at the time of inoculation.

December 21st: Inoculation was made at 1:30 P.M. 2:45 P.M.: Temperature, 99.8° F.; pulse, 144; 7 P.M.: Temperature, 102° F.; pulse, 152.

December 22d: He was restless through the night. He snuffles. 9 A.M.: Temperature, 102° F.; pulse, 144. The eyes are heavy, with purplish rings beneath. There is no rash or sore throat. Camphor and hot water brought out no rash. 7 P.M.: Temperature, 103° F.; pulse, 136. Aconite was given through the night.

December 23d, 9:30 A.M.: Temperature, 101.4° F.; pulse, 146. There is no rash. The point of inoculation is purplish and not very painful. The patient had three yellow stools during the night. 6:30 P.M.: Temperature, 103° F.; pulse, 136. There is no rash. The throat is normal. The point is purplish.

December 24th, morning: Temperature, 101.4° F. The skin and throat are normal. He had four stools during the night. Afternoon: Temperature, 101.6° F.; pulse, 152. There is a faint suspicion of rash on the inside of the thighs and chest. The abscess at point of inoculation opened early in the afternoon. He had five watery stools.

December 25th, morning: Temperature, 100° F.; pulse, 136. The rash is faint, but characteristic. The throat is slightly red. Afternoon: Temperature, 100.2° F.; pulse, 142. There is a slight desquamation around the point of inoculation. He had six watery stools during the night.

December 26th, morning: Temperature, 100° F.; pulse, 160. Afternoon: Temperature, 101.4° F.; pulse, 120. The throat is normal. The rash is still visible. He had six stools through the night.

December 27th, morning: Temperature, 100.6° F. Afternoon: Temperature, 102° F. The rash has faded.

December 28th, morning: Temperature, 102.2° F. Afternoon: Temperature, 102.2° F. The throat and skin are normal. The urine is lessened in quantity. He had five watery stools.

December 29th, morning: Temperature, 101.2° F. Afternoon: Temperature, 100.4° F. The child is white and doughy-looking, with dark lines under the eyes. He passed urine three times, lessened in quantity, acid; no albumin. The pulse tension increased. The second sound of the heart is somewhat exaggerated.

December 30th, morning: Temperature, 98.4° F. Afternoon: Temperature, 98.6° F. His general appearance is better. He passed urine twice; it is acid; no albumin. The stools are watery. The heart and pulse are normal.

December 31st, morning: Temperature, 98.6° F. Afternoon: Temperature, 98.6° F. His general appearance is fairly good. Urine was passed once during the night. The patient had three watery stools. Pulse, higher tension.

January 1st, morning: Temperature, 98.4° F. Afternoon: Temperature, 98.4° F. Urine was passed once during the night. There is desquamation in fine scales on the thighs and chest.

January 2d, morning: Temperature, 98.2° F. Afternoon: Temperature, 97.4° F. The urine is about normal in quantity.

January 3d, morning: Temperature, 97° F. Afternoon: Temperature, 101.8° F. He had two stools. The urine is normal.

After January 4th nothing occurred worthy of note. Desquamation was slight and cleared about January 10th.

CASE IX.—Mamie Smith, aged twenty-three months; health normal at time of inoculation.

December 21st: Inoculation at 1:30 P.M. 2:45 P.M.: Temperature, 100.4° F.; pulse, 120. 7 P.M.: Temperature, 100.4° F.; pulse, 152.

December 22d, 7 A.M.: There was a rash over the anterior and lateral surfaces of the chest, patchy but distinct. The throat is reddened, and the tonsils and uvula are slightly swollen. 9 A.M.: Temperature, 100° F.; pulse, 148. 7 P.M.: Temperature, 100.8° F.; pulse, 144.

December 23d, at 9:30 A.M.: Temperature, 99.2° F.; pulse, 128. 6:30 P.M.: Temperature, 100.8° F.; pulse, 144. The tonsils are red and slightly swollen. The rash is faint, but fairly continuous on the chest, abdomen, and arms. The point of inoculation is pimpled in the centre and elevated.

December 24th, morning: Temperature, 99.2° F.; pulse, 128. Afternoon: Temperature, 102.6° F.; pulse, 140. The throat is normal. The rash is unchanged. The arm and hand are swollen, although the point of inoculation is not tender except on pressure. The rash is fading.

December 25th, morning: Temperature, 101° F.; pulse, 128. Afternoon: Temperature, 100.4° F. The rash is fading, but is still red on the genitals and thighs, where desquamation is well begun. The inoculated arm is hot and much swollen.

December 26th, morning: Temperature, 99° F.; pulse, 112. Afternoon: Temperature, 99.6° F.; pulse, 120. The hand and arm are less swollen. The urine is acid, copious in quantity, and contains considerable pus and epithelium.

December 27th, morning: Temperature, 98.2° F.; pulse, 120. Afternoon: Temperature, 99.4° F.: pulse, 160. The abscess at the point of inoculation opened at 1:30 P.M., and much pus was discharged. The urine is normal.

December 28th, morning: Temperature and pulse normal. Afternoon: Temperature, 97.2° F.; pulse, 128. The rash has wholly faded. The abscess is healing. There is desquamation in large plates on the thighs.

December 29th, morning: Temperature, 97.2° F.; pulse, 136. Afternoon: Temperature, 99.2° F.; pulse, 124. The patient is desquamating in fine scales on chest and in large flakes around the point of inoculation.

December 30th, morning: Temperature, 97.4° F.; pulse normal. Afternoon: Temperature, 98.4° F.; pulse normal.

December 31st, morning: Temperature, 98.4° F.; pulse normal. Afternoon: Temperature, 98.2° F.; pulse normal.

After January 1st nothing occurred worthy of note, except between January 2d and January 9th, when some pus and epithelium were found in the urine. Desquamation ceased about January 23d.

CASE X.—George Carter, aged three years. The patient was normal at the time of inoculation.

December 21st: Inoculation at 1:30 P.M. 2:45 P.M.: Temperature, 100.6° F.; pulse, 104. 7 P.M.: Temperature, 99.2° F.; pulse, 120.

December 22d, 9 A.M.: Temperature, 101° F.; pulse, 148. He vomited without apparent nausea. The patient looks heavy. Scarlatinal rash is apparent by daylight over the trunk. The face is flushed. The throat, tonsils, and uvula are distinctly red and swollen. There is marked inflammation at the point of inoculation. 2 P.M.: There is eruption on the legs and arms. The cervical glands are a little large. He is lively, but fretful. There is slight pain on swallowing. 7 P.M.: Temperature, 100.4° F.; pulse, 136.

December 23d, 9:30 A.M.: Temperature, 99.4° F.; pulse, 152. There is a rash all over the body, but slight on the face. The throat is normal. 6:30 P.M.: Temperature, 100.4° F.; pulse, 136. The rash is brilliant red. The point of inoculation is elevated in the centre, with the base broad, hard, and inflamed. The child is fretful but lively.

December 24th, morning: Temperature, 99.4° F.; pulse, 152. Afternoon: Temperature, 103° F.; pulse, 144. The rash is unchanged. The point of inoculation is purplish-red. The arm and hand are swollen.

During the afternoon the abscess at the point of inoculation broke and discharged some foul-smelling pus.

December 25th, morning: Temperature, 100° F. Afternoon: Temperature, 99.6° F.; pulse, 124. The rash is unchanged. The abscess is slowly healing. The hand and arm are still much swollen. The hand is beginning to desquamate.

December 26th, morning: Temperature, 100.2° F.; pulse, 132. Afternoon: Temperature, 99.6° F.; pulse, 116. The rash is beginning to fade. The hand and arm are about normal. The rash was rapidly fading later in the day. There is desquamation around the point of inoculation. He passes a large quantity of water.

December 27th, morning: Temperature, 99° F.; pulse, 112. Afternoon: Temperature, 99.6° F.; pulse, 102. The rash is nearly gone. The abscess is healing rapidly.

December 28th, morning: No record of temperature. Afternoon: Temperature, 99.4° F. The rash has faded.

December 29th, morning: Temperature, 98.6° F. Afternoon: Temperature, 99.6° F. There is desquamation on the elbows.

December 30th, morning: Temperature, 99.2° F. Afternoon: Temperature, 99.6° F. Desquamation is taking place on the trunk.

December 31st, morning: Temperature, 99.6° F. Afternoon: Temperature, 99.6° F. The inoculated arm is desquamating much more than the other. After January 1st nothing occurred worthy of note, except that on January 4th the abscess at the point of inoculation began discharging anew, and continued doing so until January 12th. The hands desquamated at least twice, and the process was not finally finished till about February 10th.

The time after appearance of the eruption that desquamation began was as follows: Case I., nine days; Case II., eight days; Case III., eight days; Case IV., eight days; Case V., eight days; Case VI., five days; Case VII., eight days; Case VIII., seven days; Case IX., three days; Case X., three days. Average time, 6.7 days; longest time, nine days; shortest time, three days.

Duration of the period of incubation in the various cases: Case I., twelve hours; Case II., forty-eight hourse; Case III., forty-eight hours; Case IV., thirty-six hours; Case V., eighteen hours; Case VI., twenty hours; Case VII., twenty-nine hours thirty minutes; Case VIII., seventy-two hours; Case IX., twenty-two hours thirty minutes; Case X., fifteen hours thirty minutes. Average duration of incubative period, thirty-two hours and thirteen minutes.

Vomiting occurred as follows, as to frequency and time: Case I., vomited in twelve hours; Case II., twelve hours; Case III., six hours; Case IV., twelve hours; Case V., fifteen hours; Case VI., nausea in twelve hours thirty minutes; Case VII., no vomiting or nausea; Case VIII., no vomiting or nausea; Case IX., no vomiting or nausea; Case X., vomiting in nineteen hours thirty minutes. Average time of vomiting, twelve hours and fifty minutes after inoculation.

Temperature range: Case I.—Highest temperature, 102.5° F.; lowest temperature, 98° F.; average temperature, 99.37° F. Case II.—Highest temperature, 101.2° F.; lowest temperature, 98.5° F.; average temperature, 99.7° F. Case III.—Highest temperature, 99.8° F.; lowest temperature, 98.5° F.; average temperature, 99.03° F. Case IV.—Highest temperature, 101° F.; lowest temperature, 98.5° F.; average temperature, 99.3° F. Case V.—Could not get temperature. Case VI.—Highest temperature, 101.8° F.; lowest temperature, 100.4° F.; average temperature, 101.1° F. Case VII.—Highest temperature, 101.8° F.; lowest temperature, 97.4° F.; average temperature, 99.6° F. Case VIII.—Highest temperature, 103° F.; lowest temperature, 97° F.; average temperature, 100° F. Case IX.—Highest temperature, 102.6° F.; lowest temperature, 97.2° F.; average temperature, 99.3° F. Case X.—Highest temperature, 103° F.; lowest temperature, 98.6° F.; average temperature, 98.6° F. The average temperature of the nine cases in which the temperature was taken was 99.22° F.

Conclusions: (1) The mucus of the throat and mouth has been shown with absolute certainty to contain the contagium of the disease. (2) The early eruptive stage of scarlatina is exceedingly infectious because of the presence in the discharges from the mouth and throat of the special poison of the disease. (3) The contagium of the disease being in the mouth and throat secretions, care should be taken not only to disinfect these parts as perfectly as possible, but to keep the tongue, mouth, and lips moist constantly, if possible, in order to prevent the contagious principle being forced into the air of the room by the exhalations of the patient. (4) Mouth and nose wipes should be used instead of spit-cups and costly handkerchiefs, and they should be destroyed by fire before the discharges on them dry, *i.e.*, at once. If fire be not available, disinfecting solutions should be used strong enough to render the poison inert. (5) The soiling of the bed-clothing and personal apparel with mouth discharges should be prevented if possible. In the event of such contamination, they should be disinfected as soon as possible. (6) No toys or implements of any sort that cannot be boiled or subjected to the strongest germicidal solutions should be given the patient, as they are apt to become soiled by the mouth secretions. (7) Those who minister at the bedside should be especially careful as to personal contamination and disinfection from the moment they enter the room. (8) The nostrils should be taken thorough care of, as the morbific matter which finds its way into these parts will, in the dry state, easily find its way into the atmosphere of the room, thus making the spread of the disease more probable.

## ON OZONE AND ITS GENERATON BY THE STATIC CURRENT FOR THERAPEUTIC USE.

By J. MOUNT BLEYER, M.D., LL.D.,

NEW YORK.

Ozone has attracted a great amount of attention from chemists and meteorologists. The vague ideas which were formed as to its nature, when it was first discovered, have given place gradually to more definite views; and, though we cannot be said to have thoroughly mastered all the difficulties which this strange element presents, yet we already know much that is interesting, instructive, and valuable from many points.

Let us briefly consider the history of ozone. Nine years after Priestley had discovered oxygen, Von Marum, the electrician, noticed that when electric sparks are passed through that gas a peculiar odor is evolved; most people know this odor, since it is always to be recognized in the vicinity of an active electrical machine, and after a heavy thunder-storm. In reality it indicates the presence of ozone in the air; but for more than half a century after Von Marum had noticed it, it was supposed to be the "smell of electricity."

In 1840 Schoenbein began to inquire into the cause of this peculiar odor. He presently found that it was due to some change in the oxygen, and that it could be produced in many ways. Of these the simplest and in some respects the most interesting is the following: Take sticks of common phosphorus, scrape them until they have a metallic lustre, place them in this condi-

tion under a large bell-jar, and half cover them with water. The air in the bell-jar is soon charged with ozone, and a large room can readily be supplied with ozonized air by this process. Schoenbein set himself to inquire into the properties of this new gas, and very interesting results rewarded his researches. It became quite clear, to begin with, that whatever ozone might be, its properties were perfectly distinct from those of oxygen. Its power of oxidizing or rusting metals, for example, is much greater than that which oxygen possesses. Many metals which oxygen will not oxidize at all, even when they are at a high temperature, submit at once to the influence of ozone. But the power of ozone on other substances than metals is equally remarkable. When air, for instance, is so ozonized as to be respirable for only a short time, its destructive power is such that gutta-percha and India-rubber tubings are destroyed by merely conveying it. The bleaching and disinfecting powers of ozone are very striking. Schoenbein was at first led to associate them with the qualities of chlorine gas, but he soon found that they were perfectly distinct.

It had not yet been shown whether ozone was a simple or a compound gas. If simple, of course it could be but another form of oxygen. At first, however, the chances seemed against this view, and there were not wanting skilful chemists who asserted that ozone was a compound of the oxygen of the air with the hydrogen which forms an element of the aqueous vapors nearly always present in the atmosphere. Since the discovery of another element in the air (argon) we cannot tell how much this one will add to elucidate the many questions before us regarding the composition of the atmosphere. It was important to set this question at rest. This was accomplished by the labors of De la Rive and Marignac, who proved that ozone was simply another form of oxygen. Here we touch on a different branch of modern chemical research. The chemical elements being recognized as the simplest forms of matter, it might be supposed that each element would be unchangeable in its nature. That a compound should admit of a change is, of course, a thing to be expected. If we decompose water, for instance, into its component elements—oxygen and hydrogen—we may look on these gases as exhibiting water to us in another form; and a hundred instances of the sort might be advanced by which, either by separating the elements of a compound or by rearranging them, we obtain new forms of matter without any real change of substance; but with an element the case, one would suppose, should be different. However, the physicist must take facts as he finds them; and among the most thoroughly recognized chemical facts we have this one, that elementary substances may assume different forms. Chemists call the phenomenon "allotropy." A well-known instance of allotropy is seen in red phosphorus. Phosphorus is one of the chemical elements, and, as every one knows, the form in which it is usually obtained is that of a soft, yellow, semi-transparent solid, somewhat resembling beeswax in consistence, poisonous, and readily taking fire. Red phosphorus is the same element, yet it differs wholly in its properties. It is a powder, it does not readily take fire, and it is not poisonous. Ozone, then, is another form of oxygen. It is the only instance yet discovered of gaseous allotropy. And yet we have to deal with the difficult and still vexed questions of the way in which the change from oxygen has brought about the actual distinction between the two forms of the same gas. Schoenbein held that common oxygen is produced by the combination of two special forms of oxygen, the positive and the negative, or, as he called them, ozone and antozone. He showed that in certain conditions of the air the atmospheric oxygen exhibits qualities which were the direct reverse of those which ozone exhibits, and were distinct from those of ordinary oxygen. In oxygen thus negative or antozonized, animals cannot live any more than they can in nitrogen. The products of decomposition are not only not destroyed as by ozone, but seem subjected to preservative influences, and speedily become singularly offensive; dead animal matter rapidly putrefies, and wounds show a tendency to mortification. But the theory of positive and negative forms of oxygen has given way before the advance of new and sounder modes of inquiry. It has been proved, in the first place, that ozone is denser than ordinary oxygen. The production of ozone is always followed by a contraction of the gas' volume, the contraction being greater or less according to the amount of oxygen which has been ozonized. Regularly as the observers—Messrs. Andrews and Tait—converted a definite proportion of oxygen into ozone, the corresponding contraction followed, and as regularly was the original volume of the gas restored when, by the action of heat, the ozone was reconverted into oxygen. And now a very singular experiment was made by the observers, with results which proved utterly perplexing to them. Mercury has the power of absorbing ozone, and the experimenters thought that if, after producing a definite contraction by the formation of ozone, they could absorb the ozone by means of mercury, the quantity of oxygen which remained would serve to show them how much ozone had been formed, and thence, of course, they could determine the density of ozone. Suppose, for instance, that we have one hundred cubic inches of oxygen, and that by any process we reduce it to a combination of oxygen occupying ninety-five cubic inches. Now, if the mercury absorbed the ozone and we found that there only remained eighty-five cubic inches of oxygen, we could reason in this way: ten cubic inches were occupied by the ozone before the mercury absorbed it; but these correspond to fifteen cubic inches of oxygen; hence the ozone must be denser than oxygen in the proportion of fifteen to ten, or three to two. And, whatever result might have followed, a real absorption of the ozone by the mercury would have satisfactorily solved the problem. But the result actually obtained did not admit of interpretation in this way. The apparent absorption of the ozone by the mercury—that is, disappearance of the ozone from the mixture—was accompanied by no diminution of volume at all. In other words, returning to our illustrative case, after the absorption of the ozone from the ninety-five cubic inches occupied by the mixture there still remained ninety-five cubic inches of oxygen; so that it seemed as though an evanescent volume of ozone corresponded in weight to five cubic inches of oxygen. This solution, of course, could not be admitted, since it made the density of ozone infinite. The explanation of this perplexing experiment is full of interest and instruction. The following is the account given by Mr. C. W. Heaton (professor of chemistry at Charing Cross Hospital), slightly modified by me, however, so that it may be more readily understood: Modern chemists adopt, as a convenient mode of representing the phenomena which gases exhibit, the theory that every gas, whether elementary or compound, consists of minute molecules. They suppose that these molecules are of equal size and are separated by equal intervals so long as the gas remains unchanged in heat and density. This view serves to account for the features of resemblance presented by all gases. The features in which gases vary are accounted for by the theory that the molecules are differently constituted. The molecules are supposed to be clusters of atoms, and the qualities of a gas are assumed to depend on the nature and arrangement of these ultimate atoms. The molecules of some ele-

ments consist of but a single atom; the molecules of others are founded by pairs of atoms; those of others by triplets, and so on. Again, the molecules of compound gases are supposed to consist of combinations of different kinds of atoms. Now, Dr. Odling, to whom we owe the solution of the perplexing problem described above, thus interpreted the observed phenomena: A molecule of oxygen contains two atoms and one of ozone contains three, and the oxidizing power of ozone depends on the ease with which it parts with its third atom of oxygen. Thus, in the experiments which perplexed Andrews and Tait, the mercury seemed only to absorb the ozone; in reality it converted the ozone into oxygen by removing its third atom. And now we see how to interpret such as we considered in our illustrative case. Five cubic inches of oxygen gave up their atoms, each atom combining with one of the remaining oxygen doublets, so as to form a set of ozone triplets. Clearly, then, fifteen cubic inches of oxygen were transformed into ozone. They now occupied but ten cubic inches; so that the mixture, or ozonized oxygen, contain eighty-five cubic inches of oxygen and ten of ozone. When the mercury was introduced, it simply transformed all the ozone triplets into oxygen doublets, by taking away the odd atoms from each. It thus left ten cubic inches of oxygen, which, with the remaining eighty-five, constituted the ninety-five cubic inches observed to remain after the supposed absorption of the ozone. It follows, of course, that ozone is half again as heavy as oxygen.

But, as Mr. Heaton remarked, "This beautiful hypothesis, although accounting perfectly for all known facts, was yet but a probability. One link was lacking in the chain of evidence, and that link M. Soret has supplied by a happily devised experiment." Although mercury and most substances are capable only of converting ozone into oxygen, oil of turpentine has the power of absorbing ozone in its entirety. Thus, when the experiment was repeated with oil of turpentine in place of the mercury, the ozone was absorbed, and the remaining oxygen, instead of occupying ninety-five inches, occupied but eighty-five. After this no doubt could remain that Dr. Odling's ingeniously conceived hypothesis was the correct explanation of Messrs. Andrews and Tait's experiment. We recognize, then, in ozone a sort of concentrated oxygen with this peculiar property: it possesses an extraordinary readiness to part with its characteristic third atom and so disappear as ozone, two-thirds of its weight remaining as oxygen. It is to this peculiarity that ozone owes the properties which render it so important to our welfare. Not until quite recently have we confidently adopted Schoenbein's views that ozone exists in our atmosphere. Some disputes originated regarding the test for ozone made by its discoverer. They, however, were cleared up by other experimenters, and now there is no further doubt that the test papers which Schoenbein made use of turned blue under the influence of ozone; but they were similarly influenced by other elements which are known to exist in our atmosphere, and were turned blue even by the sun's rays. However, Dr. Andrews has shown how the character of the air producing the change can be further tested so as to render it certain that ozone has been at work on the Schoenbein test. If air which colors the test papers is found to lose the property after being heated, the change can be due only to ozone, because nitrous and nitric acids (which have the power of coloring the test papers) would not be removed by the heat, whereas ozone is changed by heat into oxygen. Once we are certain that ozone exists in the air, we must recognize the fact that its presence cannot fail to have an important bearing on our health and comfort, for ozone is an exceedingly active agent and cannot exist anywhere without setting busily to its own proper work. What that work is and whether it is beneficial has been considered, and all proofs point to the utmost beneficial side. In the first place, ozone—this pure vivifier—is found in greater abundance in pure country air than it is in the less pure air of towns and cities. It is more abundant in the mountains than in valleys, at the seaside than inland, in well drained and ventilated towns than in those where important sanitary regulations are neglected.

Air of pure quality is nature's great deodorizer and purifying principle, that oxidizes the emanations from decomposing animal and vegetable substances with which the air is constantly tainted, thus rendering them innocuous. The atmosphere would be so polluted by its admixture with the noxious matters evolved during the putrefactive changes which are unceasingly taking place on the globe as to be unfitted for sustaining animal life, were it not for the all-pervading influence of the great "disinfectant"—ozone. In thus sustaining the salubriousness of the atmosphere by destroying its impurities in its turn, it too suffers destruction. If it was not so, there would necessarily be an accumulation of ozone prejudicial to animal and vegetable life, for it is always being produced, not only on the surface of the planet, but in the wondrous envelope which encompasses it. As ozone has been considered the greatest scavenger of the air when contaminated with effluvia from the dead, it has also been thought to be the physical purifier of the living animal. Schoenbein believed that oxygen undergoes chemical polarization in the body when it is respired, and accounts in this manner for the rapid changes which occur in the tissues. It is very probable that when oxygen gas is brought into contact with the blood of the lungs, a portion of it is transformed into ozone. Some think that it is absorbed in conjunction with the ozone contained in the inspired air, and is carried by the blood into the various tissues of the organism, where it is engaged in the oxidation of effete material. This point is one of extreme interest both to the physiological and pathological student.

As ozone is so universally found to be abundant on the windward and deficient on the leeward side of the cities and towns, we are almost unanimous in thinking that it is used up in the destruction of organic matters, and that those substances which hinder the formation of ozone, if they exist in large quantities in the air, are not conducive to health, but rather to disease. It is probable that ozone possesses the power of destroying the infinitesimal germs or spores with which this organic matter is often associated, and which are in all probability the agents concerned in the spread of many diseases.

On the mountain, on the moor, at the seaside—in one word, in the bright and beautiful country which God made, where pure, invigorating air largely supplied with ozone abounds, in which the laborer, the farmer, and the fisherman are nearly always bathed—the skin is of a rosy hue and is tanned on exposure. Men and other animals are cheerful, and living things present, for the most part, a healthy appearance, while sthenic forms of diseases are encountered. The sailor, who is more exposed than the landsman to an ozoniferous atmosphere, presents this weatherbeaten and tanned appearance in the highest degree. We find on the contrary, again, in the confined and crowded dwellings of "the great unwashed" which form the great centres of industry made by man—where ozone cannot penetrate, or, if it occasionally does, where it is immediately used up in that oxidation of noxious emanations—men and plants become blanched. The skin exhibits a pallor, and all living creatures look

sickly and melancholic, while diseases of the asthenic type predominate. Writers have ventured to argue that, because ozone removes noxious odors, therefore it must arrest infection and destroy pestilental miasmata as well as the germs of epidemic disease. Hence it has been termed "nature's grand disinfectant."

Perhaps the most striking proof ever given of its qualities in this respect is that afforded by an experiment conducted by Dr. Benjamin W. Richardson. He placed a pint of blood, taken from an ox, in a large wide-mouthed bottle. The blood had then coagulated, and it was left exposed to the air until it had become entirely redissolved by the effects of decomposition. At the end of a year the blood was put into a stoppered bottle and set aside for seven years. "The bottle was then taken from its hiding-place," says Dr. Richardson, "and an ounce of the blood was withdrawn. The fluid was so offensive as to produce nausea when the gases evolved from it were inhaled. It was subjected by Dr. Wood to a current of ozone. For a few minutes the odor of ozone was destroyed by the odor of the gases from the blood; gradually the offensive smell passed away; then the fluid mass became quite sweet, and at last a faint odor of ozone was detected, whereupon the current was stopped. The blood was then entirely deodorized; but another and most singular phenomenon was observed. The dead blood coagulated as the products of decomposition were removed, and this so perfectly that from the new clot that was formed serum exuded. Before the experiment commenced it was predicted, on theoretical grounds, that secondary coagulation would follow on purification, and this experiment, as well as several others afterward performed, verified the truth of the prediction."

It will of course be understood that ozone, in thus acting as a disinfectant and rejuvenator, is transformed into oxygen. It parts with its third atom as in the mercury experiment, and so loses its distinctive peculiarity. Ozone has certain work to do, and in doing that work is transmuted into oxygen. It follows then that when there has been much work for ozone to do, we shall find little ozone left in the air, unless it is supplied continuously by such means as I speak of here. These are actual facts as recorded by strict scientific observations.

So far as we have gone, we might be disposed to speak unhesitatingly in favor of the effects produced by ozone. We find further evidences of the good effects of ozone in the fact that cholera and other epidemics never make their dreaded appearance in that land where the air is well supplied with ozone, or in what the meteorologists call "the ozone periods." And though we cannot yet explain the circumstances quite satisfactorily, we yet seem justified in ascribing to the purifying and disinfecting qualities of ozone our freedom at those times from epidemics to which cleanliness and good sanitary regulations are notedly inimical.

I have ascertained from many clinical and experimental tests that ozone is very energetic in its affinities and very powerful in its action, when artificially prepared, and that it has considerable remedial virtues in the treatment of all bacterial diseases, etc.

**Résumé of Some of My Scientific Researches on the Creation of Ozone in the Blood Circulation.**—All kinds of pitched battles have been waged in vain alone against that ravaging malady known as tuberculosis. I shall speak only of this disease here, as I devoted much time to it in trying to ferret out a scientific method of procedure against it. Many methods by others have been tested and are still to be. Some of them are based on scientific planes and others are speculative inferences. At the last conference of the International Medical Congress held at Moscow, Russia, in 1897, I presented my original research on "The Sterilization of Lung Tissue in Disease" by means of the galvanic current, etc. Now what I said in that paper was taught me by my experiments, and it seemed to all rational reasoning a most scientific and sound exposition—was founded on true physiological principles. I based my investigation on the fact that the blood is the true nourisher of the entire system, and holds in suspension all vital principles to carry on its physiological functions, and in health must always remain in as normal condition as possible. In tuberculosis, a known constitutional disease, the system is invaded early in the malady through the circulation by certain poisonous substances, which are so complex in their nature that they even defy chemical analysis (though there are some disputed points in connection with these essential tuberculous toxins existing in the blood). These so-called toxins bring about intoxications in the case of which the many methods of treatment directed against this wholesale poisoning have proved to be failures.

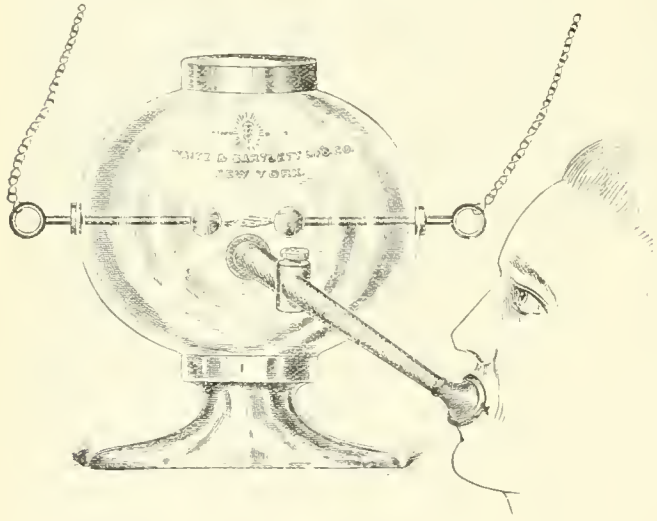
Electrolysis is a positive scientific fact; electrochemistry and electro-physiology teach us that all complex bodies can be resolved into their elementary states. Why not, then, direct its specific action on the dead tissues within the lungs and against the poisonous material floating in the blood stream? I have for a number of years struggled experimentally with several interesting and worthy electro-physiological and electro-chemical problems directed toward the specific action on tuberculosis, as the underlying principles therein are to attain results not possible to be gained by any other known method to date. I have experimentally investigated in detail the influence of the galvanic current in promoting the formation of ozone within the blood—and that with the utmost satisfaction, both clinically and scientifically.

In my communication before this congress, after giving an interesting résumé of our knowledge of the nature of ozone and its occurrence in the blood, and discussing generally the physiological and chemical factors bearing upon my investigation, I related the steps taken and the results attained by my inquiry. In order that the tests for ozone might be applied "in the open"—that is, in the free air of the laboratory, rather than in Schmitt's balloon—the inquiry was not undertaken until it was satisfactorily proved that ozone and nitrous acid, the presence of which would have invalidated my conclusion, were absent, or only present in a negligible quantity. The blood selected for examination was taken from the carotid arteries of healthy rabbits. The blood serum, as well as the fibrinous clot, gave well-marked ozone reactions, and the latter, owing to the entangled red corpuscles, more distinctly than the former. A galvanic current, with specially arranged mechanical contrivances, of ten volts and fifteen milliamperes, sent through the fibrinated blood, notably increased the amount of ozone. Although an exact quantitative test could not be well made, I approximately determined that the amount of ozone, after electrization, was increased about two and one-half times. So much for the results obtained from extravasated blood. A current of a strength of forty milliamperes was then passed through the body of a healthy rabbit for ten minutes, and blood from the carotid arteries was tested for ozone. To my astonishment the reactions indicated a considerable increase in the quantity of ozone over that obtained from normal blood. From this result it is concluded that the polarizing action of animal electricity has an important influence *in corpore* in promoting the evolution of ozone. Some interesting observations were made upon animal electricity, which

I am disposed to regard as the factor in all the processes of change, of chemical action or otherwise, within the living body.

From my conclusions after all my investigations I arrived at a point where theory and practice have become one. The theory formulated was as follows: That ozone is generated in the blood stream, but that it cannot exist there for any length of time in a free state, but that the molecules as formed, $O_3$, are readily transformed into $H_2O_2$, which would coagulate the albuminous matter and partly with the oxyhæmoglobin form probably a compound which I provisionally desire to call peroxyhæmoglobin. From the many tests I think that the galvanic current, as it passes through the blood, decomposes the chlorides (which are normal constituents) and forms hypochlorites, or some highly oxidized compounds of chlorine. In these experiments I have dealt entirely with ozone generated from the oxygen within the body, and it is in this form that it plays an important rôle in the oxidization of the tissues. I prefer to regard it as an agent that performs its most useful work upon the field where it is ushered into existence, where nature calls it into life because it is needed to perform important duties.

The tincture of chloride of iron gives the best results in combination with the inhalation of ozone or the application of the galvanic current over the stomach and front of the chest wall one half-hour after the dose has been given. It is wonderful to witness in a short time the grand effects of iron and ozone upon anæmic patients. The micrometric scale will show the increase of corpuscles in from one to two weeks in a remarkable manner.



In patients who are not able to go to mountain resorts the administration of ozone daily will give comparatively fair results.

I could cite a hundred more clinical facts, but this paper does not admit of more than I already have given as examples.

The ozone generator consists of a glass globe which has two poles within it, attachable by chains to a static machine. These poles have silver points so arranged as to produce a fine and large brush discharge which gives off a large quantity of ozone. Knowing that such a discharge in a globe does not give off pure ozone, as it contains some of the irritating acids in the air which are always intermixed, I was led to construct this compound ozone generator, by which means the ozone is purified by an oil which absorbs all impurities and allows it to pass on in a pure and administrable state. A small reservoir is attached just outside of the globe, which may be charged by a saturated piece of cotton containing any of the essential oils—giving the ozone thereby a more pleasant and therapeutic value. This is the most simple ozone apparatus ever constructed for attaching to a static machine, for generating a large quantity of pure ozone at a moment's notice.

I have also constructed a cabinet apparatus which is so arranged as to give in combination ozone and actinic rays of light of a high violet. This cabinet is big enough to permit two people to enter at one time to inhale nascent ozone and enjoy sunlight on rainy or cloudy days, etc., for any length of time.

### INTERSTITIAL PREGNANCY, AND REPORT OF CASE.

By CHARLES F. SMITH, M.D.,

Des Moines, Iowa.

The study of ectopic gestation has been so thoroughly written up in the past few years, and is of so common occurrence, that a consideration of the subject as a whole might be out of place for me; but the interstitial variety is so rare that I feel it my duty to report the following case which occurred in my practice a short time ago. About midnight I was summoned to see a woman, twenty-four years of age, of Swedish descent, married one year; her previous health had been good, with good family history; she had menstruated regularly until the past two months, since which time she had seen no show, nor had there been any discharge of any kind from the vagina. The night previous to my being called the patient had been to a ball, danced the greater part of the night, and ate a hearty supper late. The next day she did a washing, baking, and scrubbing, after which she walked downtown a distance of nearly a mile. While walking on the street she was suddenly taken with a pain in the abdomen and became faint. This soon passed away and she walked home. About the same time the bowels began to move freely, and up to the time I was summoned there were four or five stools which gave her considerable pain. The abdomen was found to be distended with gases, tympanitic, and tender on pressure. The pain when the patient was at rest was not severe, but of a bearing-down nature, which led me to suspect miscarriage. Upon making a vaginal examination the uterus was found to be about double the normal size, with a soft flabby cervix, but no dilatation. The tubes, ovaries, and cul-de-sac were carefully explored, and, so far as could be ascertained, were normal. Several attacks of sharp pain came on previous to my arrival. The pulse, respiration, and temperature were normal. There having been a little difficulty between the patient and her husband, I attributed the fainting to manifestations of hysteria, and the pain to intestinal indigestion; treatment for which was given, with a request that I be notified in case she did not improve. Early the following morning, having again been summoned, I found the patient dead, she having expired a few minutes before my arrival. The belly was distended with fluid. Further history revealed that soon after I left, at midnight, the patient went to the closet, and while there gave a scream and grew faint, becoming unconscious, and remained in that condition for some time, but finally regained consciousness. Other attacks of similar nature followed, and during

the last violent convulsions occurred, after which she became conscious and died. Believing the fluid in the abdomen to be blood, probably from a ruptured ectopic pregnancy, I asked for an autopsy, which was granted.

The abdomen being opened the peritoneal cavity was found to contain three quarts of blood, most of which was fluid, but the cul-de-sac contained a large clot. After the blood was removed extensive laceration of the uterus was found, just to the right of the median line and on the posterior aspect. The tubes, ovaries, and ligaments were perfectly normal, with the exception that the right tube and ovary were drawn a little higher by the development of the uterus being slightly greater on that side. Neither tube nor ligament showed any indication of inflammation. The whole fundus of the uterus showed degeneration and thickening of the wall, a portion being very soft. A ruptured amniotic sac was found containing chorionic villi, which had no connection with the uterine cavity. This was enclosed in degenerated uterine tissue. The uterine walls in other portions were firm and normally thickened for a two months' pregnancy. The decidua had formed in the uterine cavity, and the cervix contained a mucous plug.

The etiology of these cases is somewhat obscure; but in general the conditions that are factors in producing tubal cases proper should all be considered in this variety, as the pregnancy occurs in that portion of the tube which is within the uterine wall. In the case that came under my observation the fundus of the uterus was very much degenerated and softened at the time of the rupture, and if this condition existed at the time of the conception, it is easy to see that the development would force the fecundated ovum into the fundus, it being the direction of least resistance. The diagnosis is exceedingly difficult, if not impossible, from the fact that the symptoms do not differ to any great extent from the normal. The symptoms may be all of those found in normal cases, but too much stress should not be put upon the absence of menstruation; for in this, as in other varieties of ectopic gestation, there is very often an irregular discharge, caused by the formation of the decidua in the uterine cavity. This, however, must be distinguished from membranous dysmenorrhœa. A pregnancy occurring in a bicornuate uterus is quite difficult to distinguish from the interstitial variety, but this can usually be done, especially if the rupture takes place into the peritoneal cavity. Normal cases of pregnancy complicated with myoma or fibroid of the fundus may occasionally be mistaken for interstitial pregnancy, but if careful examination is made and the history of the growth of the tumor is taken, the diagnosis may be possible in a limited number of cases. A gradual rapid development would tend to throw the evidence toward interstitial pregnancy. Rupture, as is shown by Hecker's collection of twenty-six cases, usually takes place before the sixth month, as it did in each case of his collection. The cause of rupture is probably always pressure and development of the fœtus, thinning the walls, and finally the tension becomes too great and rupture occurs. But it is not probable that many cases actually rupture from this cause alone, as undue strain by violence of some kind is usually the direct cause. Rupture may occur either into the uterine or abdominal cavity. If into the latter, which is the most frequent, death usually follows in a short time from hemorrhage; if into the uterine cavity, the fœtus may be expelled immediately, in which case very severe if not fatal hemorrhage would follow; or the fœtus might remain in the uterus and go on to term. This would be very improbable, and would occur only when the attachment of the placenta was not disturbed. The only treatment worthy of consideration is operative, and that is necessarily complete hysterectomy, unless the rupture occurs very early and is slight, in which case the hemorrhage might not be sufficient to warrant so severe a measure.

Sections of the uterus were examined by Dr. Eli Grimes, and found to present extensive parenchymatous and fatty degeneration. The parenchymatous doubtless preceded the fatty degeneration, as the area nearest the rupture was almost wholly fatty and gradually blended into parenchymatous and thence into normal tissue, at some distance from the rupture.

## SELF-INFLICTED WOUNDS IN BOTH EYES, BOTH EARS, TONGUE, AND LARYNX, LEADING TO THROMBOSIS OF THE SINUS TRANSVERSUS.[1]

By GEORGE REULING, M.D.,

PROFESSOR OF OPHTHALMOLOGY AND OTOLOGY IN BALTIMORE MEDICAL COLLEGE.

GEORGE P——, forty-one years of age, who for several weeks had been suffering from mental depression and religious hallucinations, by trade a painter but recently occupied as a watchman in a Baltimore bank building, was on June 1st brought to the eye and ear department of the Maryland General Hospital in the following condition: The sensorium was greatly depressed, suggesting deep melancholia. Repeated questions would elicit no answer save a dull groan; the facial muscles, including the frontal, were paralyzed on the right side; the eyelids on either side were greatly swollen and bluish discolored, those of the right eye being half open, those of the left firmly closed. On raising the upper lids by means of an elevator, the right eye showed a large hemorrhage in its anterior chamber, a small perforating wound of the sclerotic over the insertion of the rectus externus, and considerable protrusion of the conjunctival transition fold, owing to intra-orbital hemorrhage. The eyeball itself was also slightly forced forward, amounting to two lines as measured by Keyser's exophthalmometer. Vision of this eye was reduced to only quantitative perception, but the visional field was intact. The left eye was similarly injured, the wound of the sclerotic, however, being over the insertion of the rectus internus and extending slightly into the cornea, corpus ciliare, and iris, a small prolapse of the ciliary portion protruding through the wound. The conjunctiva was suffused by large hemorrhages, which gave the appearance of an uninterrupted blood coagulum extending around the cornea and over the lower lid. The cornea showed all across its equator an abrasion of epithelium about two lines wide. Vision of this eye was *nil*, evidently owing to the fact that the mechanical insult was sufficient to cause a total detachment of the retina.

Both ears showed on superficial inspection several small abrasions of the concha and auricles, as also some small subcutaneous blood spots and a slight swelling of the parts. The meatus externus was filled completely with coagulated blood on either side. After a gentle use of the syringe and lukewarm sterilized water, I could see that the drum in each ear was torn by an irregular wound from which particles of tympanic tissue were hanging in shreds from the fissure. The lining membrane of the meatus externus showed also superficial scratches, but was not severely torn in any place. Hearing of the right ear: Loud voice in four feet; in the left ear there was total deafness. Neither loud voice nor Rinne's test, nor the perception by bone conduction (Weber's test) elicited any evidence of hearing. I must state here, however, that

[1] Read before the Eastern Section of the American Laryngological, Rhinological, and Otological Society at Washington.

the deep melancholia of the patient, and the difficulty of making him answer my questions, made the results of the acoustic examination to my mind somewhat doubtful. The presence of blood coagulum in the middle ear did not permit me to determine the position, presence, or absence of the ossicles. On examination of the tongue a non-penetrating stab-wound was found in the centre, just at the beginning of the papillæ circumvallatæ, and from the left tonsil downward a red streak of superficial abrasion extended toward the false left vocal cord, in which it evidently spent its force, as the true vocal cord was not injured.

All the injuries described had been made with the end of a painter's medium-sized brush handle six inches in length, which the patient had trimmed to a sharp point with his pocket-knife. If we consider the systematic procedure of the man's actions, his deliberation based on the frenzied conviction that he would find forgiveness for his sins by depriving himself of those organs which he blamed for the committal of his evil deeds, we can but be astonished at how little he must have suffered while his frenzy lasted, during which each eye and each ear, together with his tongue and larynx, were successively attacked.

My treatment consisted of an iridectomy in the left eye for the purpose of removing the prolapse of the iris and admitting of a closure of the sclero-corneal wound, followed by the application of a pressure bandage over both eyes and the introduction of iodoform gauze in both ears. In order to secure mental rest, a large dose of chloral and bromide of potassium was given at 3 P.M., one hour after the patient was brought to the hospital. The temperature was normal at that time. On the evening of the same day the temperature rose to 101.5° F.; the patient tossed about in his bed and seemed disposed to tear the bandage from his eyes, so that morphine was used hypodermically, and the patient was guarded by a strong male attendant. The remainder of the first night passed off quietly, and on the next evening I noticed an improvement in the hearing of the right ear, which perceived common conversation in about four feet distance. He also counted fingers with his right eye at a distance of four feet, and he seemed to be anxious to know whether he could recover. The left eye showed no improvement in vision, though the wound was beginning to close. The left ear was also completely void of acoustic perception, either qualitative or quantitative. The patient's tongue was greatly swollen and heavily coated; the left tonsil showed a false membrane of a rust-brown hue, and fetor ex ore of a slightly gangrenous character began to develop. After ordering a mouth-wash of an antiseptic solution, including a moist piece of lint over the tongue dipped in the same solution, I bandaged the eyes again and blocked the ears lightly as before. The sensorium of the patient was greatly improved at intervals, and his concern for getting well again and his regret for his acts became quite apparent. For the next three days the improvement of the right eye and ear was quite steady; fingers could be counted in fourteen feet on the fourth day, and the conversational voice could be heard in ten feet. On the night of the fifth day the patient became delirious and almost uncontrollably violent, so that two strong men had to hold him in check from one o'clock to six o'clock in the morning, when he fell into a profound coma lasting for thirty-six hours, when death under muscular twitchings over almost every group of muscles of the body, and a strong clonic contraction of the left sterno-cleido-mastoid, occurred on the seventh day after the injury.

Post-mortem: It was with the greatest difficulty that I was permitted by the widow and sister of the deceased to open the skull and inspect the brain. On removing the calvarium a considerable venous stasis over the whole convexity of the brain was seen, so that the meningeal veins appeared almost black and very tortuous. On digital pressure it was found that the left hemisphere was somewhat softer than the right one. After the opening of the dura mater and careful dissection, the left half of the sinus transversus was found to be occupied by a grayish-red thrombus which was tightly adherent to the somewhat greenish discolored walls of the sinus. This discoloration was particularly noticeable in the fossa sigmoidea and along the sinus petrosus superior, a condition which was undoubtedly the result of a thrombo-phlebitis of the veins of the left inner ear which directly communicate with the sinus. The infection produced by the destructive stab-wound, which penetrated into the middle ear and most likely through the fenestra ovalis to the labyrinth, had undoubtedly furnished in this case the seed for either an intra-aural periostitis or an infectious thrombo-phlebitis which led to the thrombosis of the sinus transversus and its near neighbor, the sinus petrosus superior. There were a few small capillary ruptures in the immediate surroundings of the thrombosed sinus, but no abscess or larger apoplectic deposit was found. The cerebellum and medulla oblongata were normal. As the family of the deceased would not permit the removal of the os petrosum, I was obliged reluctantly to leave this interesting specimen in its original position untouched.

## TETANUS OF NINETEEN DAYS' DURATION SUCCESSFULLY TREATED WITH ANTITOXIN.

By WILLIAM M. JAMES, M.D.,
WHITESBORO, N. Y.

Hugh H. Hughes, aged forty-three years, a native of Wales; a milkman of Maynard, Oneida County, New York. On April 1, 1898, the wind blowing a gale, Mr. Hughes attempted to open a large barn door, which was fastened by a hook and short chain. The rusty hook caught him in the ulnar edge of the palm with such a grip as to carry him with the door forcibly to the side of the barn. The hook tore deeply across the palm and down between the fingers; a ragged, ugly wound was the result. He rode nearly three miles to my office to have it dressed. The location, severity, and nature of the injury were such that I then warned him of the liability to tetanus and the necessity of extra caution on his part. The wound was thoroughly and antiseptically cleansed and dressed. Contrary to advice he kept at work, and from the cold and constant shaking over the rough roads in two days he was in great trouble. His hand and arm were much swollen. There was redness of the lymphatics extending up to the body; he had high fever, and pain and loss of sleep compelled him to remain in bed. He constantly grew worse, and in about six days from the accident a stiffness of the jaws, the forerunner of tetanus, appeared. The next day there were slight tetanic spasms. For comfort to him and convenience to myself, on April 9th, about 2 P.M., he was admitted to St. Luke's Hospital of Utica. He was given a warm tub bath, and under anæsthesia the wound was thoroughly cleansed, free openings for the exit of pus being made above the wrist and near the elbow. Thorough irrigation was made with bichloride and warm water, drainage tapes were inserted, and the hand and arm were properly dressed. The dressing and thorough irrigation were repeated every six to twelve hours thereafter as indications seemed to require. At 2 P.M. the temperature was 101.2° F.; pulse, 108; respiration, 26. The man was suffering much pain and had frequent spasms at this time. At 10 P.M. the temperature

was 102.6° F.; pulse, 126; respiration, 26. He was in greater suffering from pain and had severe tetanic spasms. I began using tetanus antitoxin, 20 c.c., injected under the skin in the back.

April 10th: There was severe pain in the arm, little sleep, great difficulty in swallowing, profuse perspiration; no perceptible changes in wounds. Temperature, 100.4° to 102.2° F.; pulse, 112; respiration, 24. Antitoxin, 20 c.c., was given at 10 A.M., 5:15 P.M., and midnight.

April 11th: There was no perceptible change. Temperature, 101.8 to 100.8° F.; pulse, 84 to 104; respiration, 22 to 24. Antitoxin, 20 c.c., was given at 5 A.M.; 10 c.c. at 9:45 A.M. and 2:45 P.M.; 20 c.c. at 6 P.M. and 11 P.M.

April 12th: There was muscular twitching of the face, arms, and legs while the patient was sleeping. Temperature, 99° to 99.8° F.; pulse, 100 to 112; respiration, 20 to 22. Antitoxin, 20 c.c., was given at 6 A.M. and 10 A.M.; 5 c.c. at 2:15 P.M.; 20 c.c. at 3 and 9:30 P.M.

April 13th: The patient slept about four hours last night. There was less muscular twitching now. Tincture gelsemium gtt. x. was ordered every two hours. The supply of antitoxin getting short, its use was extended to every six hours.

April 15th: The patient is worse in every way. He received no antitoxin after 6 A.M. Tincture gelsemium gtt. v. was given every two hours.

April 16th: Temperature, 99.2° to 100.2° F.; pulse, 120 to 100; respiration, 24 to 20. There was intense pain in the muscles of the neck, arms, legs, and abdomen. The abdomen was intensely rigid so that strong pressure made no impression. This constant rigidity and pain in the muscles lasted a long time, but after the man was again well under the influence of antitoxin it disappeared.

April 17th: I began antitoxin, 20 c.c. every three hours, a little before 1 A.M., and continued in the same way throughout the day.

April 18th: The patient is a little better. Temperature, 99.8° to 98.4° F.; pulse, 124 to 106; respiration, 24 to 20. Antitoxin, 20 c.c., was given every three hours.

April 19th: Temperature, 99.8° to 98.4° F.; pulse, 124 to 106; respiration, 24 to 20. Antitoxin, 20 c.c., was given every three hours. Tincture gelsemium gtt. vi. every two hours. The patient is very much better.

April 20th: No antitoxin was given, as the supply had run out. Temperature, 98.6° to 99.4 F.; pulse, 96 to 100; respiration, 20.

April 21st: No antitoxin. Temperature, 98.6° to 99.4° F.; pulse, 110 to 120; respiration, 20. The spasms and muscular contractions were very severe, frequent, and painful.

April 22d: Temperature, 98.6° to 99.4° F.; pulse, 98 to 120; respiration, 20 to 24. Antitoxin, 10 c.c., was given at 6:45 P.M. The patient was suffering greatly.

April 23d: Temperature, 100.6° to 101.4° F.; pulse, 100 to 106; respiration, 20 to 28. The tetanic spasms were much worse. The discharge from the hand and arm having nearly ceased, the drainage tapes were removed. Antitoxin, 20 c.c., was given at 8:30 and 10:30 A.M.; 10 c.c. at 12:30, 2:50, and 5:30 P.M., and every two hours thereafter.

April 24th: Temperature, 100.4° to 100.2° F.; pulse, 100 to 104; respiration, 20 to 22. Antitoxin, 10 c.c., was given every two hours. Fluid extract gelsemium gtt. viii. every two hours.

April 25th: Temperature, 100.4° to 102.2° F.; pulse, 100 to 134; respiration, 20 to 28. The patient is very weak with profuse perspiration. Antitoxin, 10 c.c., was given every two hours.

April 26th: Temperature, 101.8° to 100.8 F.; pulse, 120 to 132; respiration, 24 to 30. He is very weak and sweating very much. Antitoxin, 10 c.c., was given every three hours.

April 27th: The patient is better, has no spasms, and sweats freely. Temperature, 101.2 to 100.4 F.; pulse, 118 to 130; respiration, 20 to 24. No antitoxin was used from this date.

April 28th: There was daily improvement. The sweating continued several days. On the 12th, the man had a tub bath. He began sitting up about the 10th, and with good nourishment and stimulants and tonics improved so as to be able to leave the hospital May 28th. The duration of the tetanic spasms was nineteen days.

On two different occasions I failed to get the antitoxin on time, and there was an interval of one and one-half days once, and over two days at another time during which the patient grew rapidly worse; the spasms were more severe and frequent, making it seem as if the result would be fatal. Upon the renewed employment of antitoxin a rapid improvement occurred, thus proving positively its benefit, and that the man's life was saved by it.

On March 20, 1899, I met the man at his usual occupation, and upon inquiry learned that he was in perfect health and has been ever since his tetanic attack. The hand is almost perfect in use.

In the past thirty-seven years as a practitioner I have seen and treated nearly thirty cases of tetanus, employing a great variety of methods, but have always seen fatal results until this latest experience.

---

## A CASE OF PRIMARY RENAL TUBERCULOSIS OF TWENTY YEARS' STANDING.

By JACOB FRANK, M.D.,

CHICAGO, ILL.,

SURGEON TO THE ST. ELIZABETH AND GERMAN HOSPITALS AND CONSULTING SURGEON TO THE JEWISH ORPHANS' HOME.

Mrs. S——, married, thirty-nine years of age. American by birth, came to my office in February, 1898, with the following history: For twenty years she had been suffering with what was called by her other physicians, according to her statements, cystitis. She had intermittent attacks of painful and frequent micturition, with pyuria and polyuria; was lame and sore, and had a burning, hot feeling in her back, especially in the region of the left kidney. On two or three occasions she had been taken very sick with colicky pains, commencing in the small of the back, radiating to the thighs; this was followed by inflammation of the urethra and by a rise of temperature, which necessitated her confinement to bed. These attacks were pronounced by her physician "inflammation of the kidneys." She never had passed any calculi. All the above symptoms began to be constant about ten years ago, and remained so up to the time I saw her, when she was obliged to wear a urinal in order to prevent irritation by the decomposed urine and discomfort resulting from the incontinence. She had undergone three operations for urethral ulcerations and one for rectal ulceration. During the entire time of her illness she was treated for bladder trouble both internally and by local irrigation.

The first part of March, when she consulted me again at my office, I recognized the chronicity of the case from its long standing. I made a cystoscopic examination, and the bladder was not found in such a condition as to account for all the above symptoms. Her ureter was catheterized with Kelly's instruments, under cocaine anæsthesia, with no striking results. A small amount of urine was collected from the left kidney,

which was clear and quite normal. From the right kidney the attempt to collect the urine was unsuccessful, as there seemed to be some swelling in the way, at the mouth of the ureter, that interfered with the introduction of the ureteral catheter.

An examination of the urine passed by the patient was made microscopically, and an abundance of pus and epithelial cells were found. Some of the sediment was stained for tubercle bacilli with positive results.

The Harris instrument was finally used, and the urine obtained from each kidney examined with the following results:

| | Right Kidney. | Left Kidney. |
|---|---|---|
| Amount collected in twenty minutes. | 8 c.c. | 10 c.c. |
| Color | Pale milky and cloudy | Clear, light amber. |
| Reaction | Neutral. | Acid. |
| Urea | 0.05 per cent. | 1.05 per cent. |
| Albumin | Well-marked quantity | Very small trace. |
| Microscopically | Pus cells and few red cells. | Few flat cells and occasional leucocytes. |

I did not examine for tubercle bacilli this time. The low percentage of urea, however, secreted by the right kidney showed clearly the degree of destruction of that organ, while the presence of the bacillus tuberculosis, together with the normal findings in the urine from the left kidney, and also the absence upon close physical examination of any lesions elsewhere in the body, made the diagnosis clear and positive of primary renal tuberculosis of the right kidney, which, strange enough, was free from any subjective symptoms and was not palpable.

About the middle of March, 1898, the patient was sent to the German Hospital for operation, when she was very emaciated and anæmic, and had a hectic fever and night sweats, which, according to her statements, she had had for many years.

On March 15, 1898, a lumbar nephrectomy was made, the right kidney and the greater portion of the ureter being removed. After operation the patient's temperature dropped to normal. She made a good recovery and was discharged from the hospital in the fifth week. She is now—which is over a year from the time of operation—feeling well. There is a small ulcer, probably tuberculous, at the neck of the bladder that troubles her considerably, giving rise to occasional attacks of hæmaturia. Except for this the patient feels well, has gained in weight, and has a good appetite.

A pathological diagnosis was made for me by Dr. L. Feingold, and the clinical diagnosis was confirmed: The kidney is very slightly enlarged, nodular; capsule adherent along the entire extent of its attachment to the kidney. Some of the nodules are fluctuating, due to an abscess cavity being located in the cortex behind the nodule. Opening the kidney along its convex surface, abscess cavities of varying sizes, from one-half to three-quarters inch in diameter, invading both the cortical and medullary substance of the kidney are seen. The abscess cavities are filled with a yellowish, cheesy pus, some of which is adherent to the cavity wall. These walls are made up of very old connective tissue and infiltrated with calcareous material, imparting to the touch a feeling of brittleness. In the vicinity of the abscess the kidney substance seems to the naked eye apparently normal. The cortical marking is present in some and absent in other places. The pelvis of the kidney is dilated and studded with young tubercles about the size of a millet seed, showing that the infection travelled downward from the kidney.

*a*, Abscess wall; *b*, three fairly old tubercles of Laennec; *c*, giant cell; *d*, young tubercle; inflammatory tissue; *f*, blood-vessel; *g*, uriniferous tubule.

A section was removed for microscopical examination from the cortex of the kidney, extending into a tuberculous cavity; it was prepared and stained with hæmatoxylin and eosin. Upon examination is noticed in the microscopic field (see accompanying illustration) at the right upper angle quite a thick fibrous capsule, which is nothing more than the wall of a tuberculous abscess. In the immediate vicinity of this fibrous tissue is found an abundance of embryonal connective tissue and three fairly old characteristic tubercles of Laennec, the structure of which consists of a peripheral fibrous-tissue zone and a fibrous-tissue trabecular framework in which characteristic giant cells are seen more abundantly at the periphery of the tubercle and somewhat concentrically arranged. These cells are large, containing from about ten to twenty nuclei which are also concentrically arranged at the periphery of the cell. The cells are distinctly protoplasmic.

In the immediate vicinity of these tubercles a few young ones can be seen and many areas of round-cell infiltration. There is one tubercle not represented in this illustration that has implicated in its meshes what appear to be some tubuli uriniferi. All this inflammatory reaction is confined exclusively to the immediate vicinity of the abscess wall above mentioned. At the left lower angle of the field, which is also seen in the illustration, some comparatively normal kidney structure is seen, becoming absolutely normal in appearance a little distance away from the seat of inflammation.

The condition of the abscess walls and the recent invasion of the pelvis of the kidney, as is learned from the pathological report, explains two features. The former explains the escape from general infection, as such a wall surrounding a tuberculous process will surely be a great barrier against general infection. The latter explains the direction of travelling infection when the pathological process of the cortex of the kidney is compared with the pathological process of the pelvis of that organ.

17 Lincoln Avenue.

## Progress of Medical Science.

**Two Distinct Fractures in the Same Patella at an Interval of Eight Months.**—Henry (*American Journal of the Medical Sciences*, August, 1899) has reported a case in which the plaintiff in a suit for damages had slipped on some loose fragment of brick and had fallen, sustaining a fracture of the left patella. Investigation disclosed that a little less than eight months previously the man had sustained a fracture of the same patella. On examination of the knee-joint a year after the accident but one fracture could be made out, and in that the union was so close and firm that in the centre no separation whatever could be felt, while at the edges the separation did not exceed one-quarter of an inch. There was in addition some slight fibrous ankylosis of the knee-joint, and also some limitation of movement due to adhesions that had formed between the upper fragment of the patella and the femur. The patella itself was much enlarged, its length measuring three and a quarter inches. The patient felt confident that the two fractures had not occurred in the same place, and that the first was nearly an inch below the second. A skiagraph exhibited clearly two separate fractures. It was accepted as evidence, and the patient gained his suit and was awarded damages.

**The Proteid of the Thyroid.**—So many observations have been made on the proteid of the thyroid gland that it might appear that definite information was not to be attained. In the *Zeitschrift für physiologische Chemie*, vol. 27, 1899, Ad. Ostwald gives the latest contribution to this much-involved question. In a thorough and exact manner he has investigated the iodine proteid of this gland. He finds that it belongs to the class of globulins, and he has suggested the name "thyreoglobulin." It may be precipitated by a half-saturated solution of ammonium sulphate from its solution in common salt, and it contains from 1.5 to 1.75 per cent. of iodine and about two per cent. of sulphur, but no phosphorus. Investigations on the pharmacological action showed that it has the same efficiency as the thyroid itself in its effects on metabolism, and there would seem to be no doubt that this globulin is the active principle sought for. This globulin and also an iodine-free nucleo-proteid is probably secreted by the epithelium of the gland and is localized in the colloid of the thyroid.

**Osseous and Articular Trophic Disorders in a Case of Spinal Muscular Atrophy.**—Etienne (*Revue de Médecine*, July 10, 1899) reports the further history of a case of progressive muscular atrophy complicated by marked arthropathies occurring in a farmer forty-eight years old. The patient had presented a tumor as large as a fœtal head, which had formed suddenly in the right axilla with severe pain, after a fall while the man was engaged in dressing. The swelling was bluish and ecchymotic, of soft, gelatinous consistence, and fluctuating. Three weeks later the tumor was still palpable as a thickened mass, but the skin had resumed its normal color and aspect, and fluctuation was only vague. There were now detected signs of incipient pulmonary tuberculosis, and several months later the right testicle was evidently tuberculous. After a time a new cuirass-shaped osteophytic process about 10 cm. in diameter was discovered at the level of the right scapulo-humeral articulation behind the site of the previous formation. The muscular wasting became extreme and the cachexia profound. Bedsores formed over the sacrum, over the clavicle where the chin rested on the chest, on the chin itself, and over both scapulæ. The left cornea also became ulcerated, and the patient eventually died from trophic cachexia. Upon post-mortem examination the axillary tumor was found on dissection to be a pouch developed in the subcutaneous connective tissue containing about a pint of brownish, turbid fluid, and communicating by a large opening with the scapulo-humeral articulation. This condition, it was thought, arose from a rupture of the synovial sac of the joint, with the escape of fluid, but without the subsequent formation of a cyst wall. The right pleural cavity contained a considerable quantity of lemon-yellow fluid, and there were numerous slight adhesions. Both lungs, as well as both testicles, were tuberculous. The capsule of the right scapulo-humeral articulation was greatly distended, and its walls were thinned. The head of the humerus had entirely disappeared. At the periphery of the articulation were a series of osteophytes corresponding to the points of attachment of the peri-articular tendons. The spinal cord exhibited no microscopic alteration. On section it presented neither gliosis nor cavity. Histologically the ganglion cells of the anterior horns, some of the peripheral nerves, and the affected muscles were found to be degenerated in varying degree.

**Pulsatory Foot Phenomenon.**—When the popliteal space of one leg is rested upon the patella of the opposite leg a rhythmic movement of the foot of the overlying member becomes visible synchronously with the pulse. This manifestation Placzek (*Berliner klinische Wochenschrift*, July 31, 1899) designates the pulsatory foot phenomenon, and he has made a graphic study of the condition. The curves in the tracings made correspond with those obtained with the sphygmograph, than which, however, they are in some respects more distinct, and when the necessary apparatus is at hand they are more easily prepared. There seems little doubt that the movement of the foot is dependent essentially upon the pulsation in the popliteal artery, although it has been suggested that it is in part a reflex manifestation. It occurs, however, in cases in which the knee jerks are wanting, and it is not increased in cases in which the patellar reflex is excessive.

**Reduction of Shoulder Dislocations.**—To prevent the paralysis which he believes to result from the pressure in the axilla made in the reduction of dislocations of the shoulder, Thomas (*Liverpool Medico-Chirurgical Journal*, July, 1899) recommends the following mode of procedure: With the patient seated on a firm stool or chair, an assistant stoops down on the left side, if the right shoulder is dislocated, and, with his left arm crossing the front of the patient's chest, places his hand firmly on the end of the right clavicle and acromion; his right arm is passed behind the patient's back and grasps with hooked fingers the axillary border of the scapula. The function of the assistant is to fix the scapula before any manipulation is commenced, and prevent the manipulator from dragging the patient off the chair (occasionally a second assistant becomes necessary to hold the first, if the muscles of the patient are powerful and the traction by the surgeon has to be kept up long). The surgeon, keeping the elbow at a right angle, grasps the wrist of the dislocated arm with his right hand and the lower end of the humerus from behind with his left hand, and locks this hand against the forearm of the patient to prevent slipping. He now quietly and slowly abducts the humerus to a right angle. Traction outward is commenced as soon as the humerus is half-way up, and is quietly but firmly continued, the operator at the same time gently rotating the humerus outward; in other words, drawing the arm out of the side and taking the hand and forearm up in the air, keeping the elbow at a right angle all the time. If the head of the

humerus does not travel from beneath the coracoid (in the case of subcoracoid dislocation), the surgeon places his own feet nearer the patient, and, while steadily pulling, fails away from the patient, thus bringing his own weight to assist traction, and in some obstinate cases slowly rocking the humerus up and down, or from side to side, to tire the powerful muscles that are resisting, chiefly of course the deltoid and the pectoralis major. In most ordinary cases the head of the bone is observed to be now in the glenoid cavity, and on account of the steady, continuous traction the head goes in without snap or jerk. If the head is not reduced by this time, rotation outward is continued until locking occurs. Rotation inward now immediately puts the humerus right; traction is at once stopped, and the surgeon slings the reduced arm to the patient's side, keeping the hand high. If this method is applied slowly and thoroughly so little pain is caused that chloroform is rarely required to relax the resisting muscles. A running conversation with the patient during the manipulation serves to distract his attention from the shoulder and cause involuntary relaxation of the muscles in the neighborhood. Chloroform is occasionally required, not on account of the size of the muscles of the patient, but only in highly strung, nervous men or women who will not bear even the slightest discomfort, still less actual pain. If an anæsthetic has been administered, the scapula is fixed in the same manner, the patient, of course, now lying down: the same traction and manipulation are gone through, but very little of each is then required. In dislocation of the left shoulder, "left" is substituted by "right" and "front" by "back" in the foregoing description.

**The Principles Governing the Treatment of Injuries of the Spinal Cord.**—As the result of personal experience with a considerable number of cases of spinal injury, Bolton (*Annals of Surgery*, August, 1899) has reached the opinion that extra-dural hemorrhage does not give rise to cord-lesions or symptoms and requires no treatment. Total lesions of the cord are irremediable, because the cells and fibres of the entire thickness of the cord are destroyed, are never regenerated, and are replaced by cicatricial tissue. The lesion thus is a permanent one and requires no treatment. In hæmatomyelia the clot is absorbed; its site persists as a cavity or is replaced by newly formed tissue; irregularities of circulation in the surrounding portions of the cord adjust themselves. There may be great amelioration of the symptoms. There is, therefore, no therapeutic indication, and no remediable treatment is possible. In partial contusion of the cord the lesion results in permanent destruction of cells and fibres; disturbances of circulation adjust themselves. Repair is effected by cicatricial-tissue formation. No treatment is available. Open injuries of the cord are attended with destruction of cells and fibres and disturbances of circulation. In addition, infection may occur, or a foreign body may be introduced and left in or be lodged against the cord and by its continued presence cause great disturbance of circulation and consequent extensive degeneration and necrosis of cells and fibres. Repair is effected by cicatricial-tissue formation. Here active operative intervention is indicated for the removal of foreign bodies, to facilitate disinfection and drainage, and to prevent more extensive necrosis.

**The Prognosis of Nephritis.**—In view of the indefiniteness and disagreement of the statements in the text-books with reference to the prognosis of nephritis, Cabot and White (*Boston Medical and Surgical Journal*, August 10, 1899) undertook a study of the records of the Massachusetts General Hospital for twenty years, with especial reference to the course and symptoms of the fatal cases of nephritis. Besides, such information was analyzed as could be secured concerning all patients that had been in the hospital during the same period of time suffering from nephritis of any type. Finally, additional information upon the same subject was obtained from a large number of physicians. In these several ways four hundred and twenty-three cases were studied. Two important types of nephritis were recognized, (*a*) chronic diffuse and (*b*) interstitial. The former is characterized by prolonged anasarca and effusions into the serous cavities, early and pronounced manifestations of uræmia, such as headache, vomiting, dyspnœa, vascular changes such as cardiac hypertrophy and a high-tension pulse, and a pale urine usually diminished in amount, containing a large amount of albumin, with an abundance of fatty elements in the urine. The second type is a disease of insidious onset and long course, with a comparatively early appearance of the vascular changes and little or no œdema until the heart fails, with late and usually less marked uræmic symptoms and a large amount of urine of low specific gravity, with albumin present in very small quantities if at all, and a sediment containing usually only a few hyaline and granular casts. Recovery was considered to have taken place when the patient was free from subjective symptoms characteristic of nephritis and passed normal urine. In a few of the cases the long duration of the symptoms and the character of the urine indicated an undoubted chronic nephritis followed by a genuine recovery. Nine cases in which there was a distinct history of lead poisoning and sixteen in which there was a history of syphilis pursued a comparatively long course. Some of the shortest cases, judged by the duration of definite symptoms, were associated with arterio-sclerosis, death resulting unexpectedly from uræmia. Fifty-seven cases in which the only possible etiological factor elicitable was heredity—that is, a family history of nephritis, dropsy, apoplexy, heart disease, or pulmonary tuberculosis—seemed to pursue a relatively long course. No relation was observed between the duration of the cases and such etiological factors as abuse of alcohol, infectious diseases, pregnancy, or exposure to cold. In the vast majority of cases no cause of any kind could be traced. Complications were the cause of death apparently in forty-four of three hundred and thirty-two cases. Pneumonia and pericarditis were the most common, and pulmonary tuberculosis next. Pneumonia was equally common as a cause of death in cases of short and of long duration, while pericarditis seemed more prone to carry off patients at a comparatively early stage of the disease. As cases of nephritis get on beyond the first year of the disease the dangers of such complications as cerebral hemorrhage, hemiplegia, and gangrene increase. The course of the disease in the cases of diffuse nephritis without dropsy was less than half as long as in cases with dropsy. Dropsy was not sufficiently common in cases of interstitial nephritis to be of much prognostic value. Cases of chronic nephritis rarely lasted more than two years after the occurrence of hemorrhage into the retina. The development of hypertrophy of the heart marked the advance of the disease beyond the curable stage. As a result of the foregoing study the following conclusions are summarized: (1) Chronic nephritis is not an absolutely incurable disease. Recovery occurs in rare instances. (2) Chronic nephritis may exist for a long series of years without causing any apparent constitutional disturbance. (3) The average duration in three hundred and thirty-two cases of chronic nephritis was nineteen months. (4) Acute nephritis is less common than has been supposed; many cases formerly diagnosticated as such have been shown to represent exacerbations in the course of chronic nephritis.

MEDICAL RECORD:

New York, September 9, 1899.

## THE PLAGUE IN EUROPE.

THE writer in *The British Medical Journal* who, judging from the progress westward of the bubonic plague in times past, declared that the recent outbreaks in Egypt and in parts of the African Mediterranean littoral tended to show that the disease was once again moving toward the continent of Europe and might there gain a foothold, may prove to have been a true prophet. His note of alarm was scoffed at by perhaps the majority of medical and sanitary authorities; nevertheless, plague has broken out in more than one part of Europe, while in Oporto matters are so serious that there is reason to fear that a centre of the disease has been established whence it may spread throughout the peninsula. The Portuguese ports, and, in fact, their towns generally, owing to the prevailing unsanitary conditions—as bad in many instances as in Eastern cities—are unfortunately peculiarly adapted to lend color to these gloomy presages. It is to be hoped, however, that the Portuguese and Spanish sanitary authorities are sufficiently conscious of their great responsibility, and that they will bestir themselves and will put into effect every possible measure calculated to avert so great a calamity as a widespread epidemic of the plague in Spain and Portugal.

In Egypt the situation shows little change. The plague is more or less *in statu quo*. The quarantine regulations are of a reassuring character. Every important European port, with the exception of Marseilles, has, according to Consul Skinner of that city, adopted strict quarantine measures against importations from Alexandria. The plague in Egypt presents some peculiar features. In the first instance, the epidemic is of an exceptionally mild nature; but the most distinctive point about it is that almost as many white persons as natives have been attacked by the malady. The belief has long prevailed—and this has been the experience in India and China—that foreigners are nearly wholly immune to plague infection. The epidemic in Lower Egypt has gone some way toward shattering this comforting illusion. So far as India is concerned the explanation of this seeming anomaly lies probably chiefly in the fact that the native sections of the towns and the native villages are in a deplorably unsanitary state, while on the other hand the Europeans resident in the East live under the best hygienic conditions possible. *The Journal of Tropical Medicine* in an editorial draws attention to this phase of the situation, and furthermore points out that many of the large centres of population, both in Great Britain and on the European continent, are regarded from a sanitary standpoint almost as bad as those of the East. The Oriental natives are undoubtedly more prone to contract the disease than the white men, but at the same time sufficient and convincing proof has already been afforded that Europe has good cause to dread an invasion of the plague.

There is, however, no cause for a panic, even if the disease does creep over Europe. It is, of course, highly desirable that it be kept out, for every death from a preventable disease is a reproach to sanitary science, but the plague is terrifying only because of its name. There is no reason to apprehend a great mortality even should it settle down in London, Paris, Berlin, or New York, and none who live in cleanly quarters and lead temperate lives need fear. If we were called upon to choose between the plague and any one of a dozen other diseases which we have always with us, we would gladly invite the former. Diphtheria kills more in a year than the plague could destroy in a civilized city in a decade, and, as some one has suggested, if we would call the disease bubonia, or any name but plague, there would be little alarm inspired by its approach.

## THE WORK OF THE MARINE-HOSPITAL SERVICE FOR 1898.

THE annual report of the Supervising Surgeon-General of the Marine-Hospital service of the United States for 1898, together with the operations of the service as regards quarantine and public health matters, fill a bulky volume of eight hundred and twenty-seven pages. The first point to be noticed is that the revision of the regulations made necessary by the increase in the scope of the service has been completed. Nearly two hundred pages of the report are taken up with articles on yellow fever, providing probably as full and as exact a description of its nature, diagnosis, treatment, and prophylaxis as has ever been published. The quarantine regulations are also dealt with at length.

Perhaps the most instructive articles are those treating of the prevention of yellow fever, and especially that of Surgeon H. R. Carter with respect to the hygienic measures to be taken in an infected town.

Concerning "daylight communication," otherwise direct communication, with an infected town during the day-time, Surgeon Carter has this to say, that it depends on two principles: (1) That the infection of yellow fever is mainly confined to the habitations of men and their environments, and (2) that the disease is not liable to be contracted in the day-time. Surgeon Carter thinks that the first proposition is unquestionably true, and that the second is true to a certain extent, and if "bright, clear day out of doors" be substituted for "day-time," probably to a very considerable extent. Another article of much value is that by Passed Assistant Surgeon Eugene Wasdin on the value of autopsical

findings in persons who have died of suspected yellow fever. Dr. Wasdin concludes with these words: "Finally I would suggest that typical autopsical findings should always be regarded with suspicion and demand immediate investigation of their cause. Should there be or not any local centre of auto-infection, there should be an investigation of the immediately preceding history of the patient, and should there prove to be evidence of exposure to infection of yellow fever, and should the clinical charts and history present the evidences of the disease which we have learned to recognize, then, and only then, can the information gained post mortem be of decisive value to the diagnostician."

On the subject of smallpox, which was more or less prevalent in 1898, the report uses the following well-judged words: "Smallpox is a disease so easily prevented by vaccination that the smallpox patient to-day is scarcely deserving of sympathy. . . . The spread of the disease also is so easily prevented under proper management that it is a disgrace to the sanitary authorities of any State, municipality, or locality whenever this disease is permitted to get beyond their control." In view of the spread of the plague from the East into Europe the report on that disease will provide interesting reading. The history of yellow fever during the war with Spain is fully dealt with.

It is satisfactory to note that the relations of the Marine-Hospital service with the State health authorities are in a high degree harmonious, and it should be said that the Marine-Hospital service has fulfilled its arduous and trying duties in the most effective manner.

## ATROPHY OF THE OPTIC NERVE FOLLOWING PROFUSE HEMORRHAGE.

It is well known that inflammatory and degenerative changes take place in the optic as well as other nerves, as a result of various toxic influences, and also, though perhaps less commonly, in conjunction with profound blood deterioration. It should, therefore, not occasion surprise that similar lesions should be induced by anæmia acutely induced by profuse hemorrhage. Cases in which this has taken place are on record, but they are of such rarity that every additional instance is of interest. Such a one is that of Theobald (*Bulletin of the Johns Hopkins Hospital*, vol. x., No. 98), who reports the case of a man, fifty-seven years old, who had presented for twenty years symptoms of gastric derangement, with frequently repeated attacks of vomiting. Following copious hemorrhage from the stomach, repeated twice at intervals of forty-eight hours, vision, which had previously been good, became greatly impaired. Subsequently there was some improvement in eyesight, but later it again grew worse. The patient admitted having been a pretty constant smoker, but denied having been a hard drinker and also having had syphilis. On exploration a nodular mass was found near and partly occluding the pyloric orifice, which was regarded as a malignant growth, developed in the cicatrix left by previous ulceration. On ophthalmoscopic examination both optic nerves were found in a state of advanced atrophy, with some cupping and marked contraction of the retinal arteries. The optic discs had a woolly appearance, their outlines were irregular and ill-defined, and in each eye there were pigment-changes in the retina, not only about the margin of the discs, but at points some distance from it, and especially in the macular region, indicating that the atrophy of the nerve had been preceded by an inflammatory process which had involved the retina as well as the optic nerve. From a study of this case, and the literature of the subject, the conclusion is reached—(1) that the weight of evidence afforded by the ophthalmoscope points to thrombosis of the central retinal artery as the usual cause of the blindness that attends post-hemorrhagic anæmia; (2) that the resistance offered to the already enfeebled blood-current in the central retinal artery by the intra-ocular tension is an important etiological factor in determining this result; (3) that, in exceptional cases, the ophthalmoscope indicates that the thrombosis occurs not in the artery, but in the central retinal vein; (4) that, in other exceptional instances, it may be that the loss of sight and the ophthalmoscopic changes that accompany it are the result of a hemorrhagic or serous effusion into the optic nerve or its sheath (Samelsohn); and here, again, the obstruction and damming back of the blood-current in the retinal artery by the intra-ocular tension, probably, have much to do with bringing about this result.

In the case reported the question naturally arises, whether the long-continued gastric derangement and the existence of malignant disease may not have been at least a predisposing factor in the development of the inflammatory and degenerative changes in retina and optic nerve.

## THE CORONER'S OFFICE AND THE DAILY PRESS.

The coroner's office in this city seems to be in a continual state of excitement concerning the way the hospitals here are conducted. Every few weeks some member of that office gets himself into print by exposing what he is pleased to call some mistake in diagnosis, or the performance of an unnecessary operation in one of these institutions. There is usually a tirade against one or more members of the hospital staff, and then the official "feels deeply that there must be a reform." Within the last few days Bellevue Hospital has suffered such an attack, and some of its staff have been held up in the daily papers as ignorant in their methods and also untruthful in their statements. In this case a boy died in the hospital soon after an operation for what the hospital surgeons diagnosed to be appendicitis. There was later elicited an extremely untrustworthy history of injury, resting largely on the evidence of a boy eleven years old, and there was an investigation by a coroner's physician, who disagreed with the surgeons at the hospital and said, according to the newspaper account, that the boy had died of peritonitis following injury. Although such an opinion was not warranted seemingly by any distinct autopsical

revelations, its public expression was an excuse for the charge that an operation for appendicitis was needlessly performed. If the critical official is correctly quoted, he has made an outrageous attack upon the professional qualifications of a portion of the staff of this particular hospital, and has included in his statement the charge that unnecessary operations are frequently performed in the "emergency" hospitals of this city. The term "emergency" in this case practically includes every active hospital in the city, and the charge that operations are done without due consideration and preparation, and unnecessarily, is malicious and absurd, and tends to undermine confidence in those institutions among the very classes to whom they are most beneficial. Possibly the members of the coroner's staff feel that unless they keep up some sort of excitement their constituents will think that they are not earning their salaries, and this feeling may account for their frequent appearances in print. A little self-restraint in this matter would be exceedingly becoming to them.

## THE TREATMENT OF SINUS-THROMBOSIS OF OTITIC ORIGIN.

Thrombotic occlusion of the cerebral sinuses arises most commonly in consequence of adjacent disease, *e.g.*, otitis, fracture, caries, erysipelas. Rarely it is a result of constitutional conditions, such as anæmia, chlorosis, marasmus, and the like. The resulting symptoms vary somewhat with the situation of the lesion and the nature of the morbid process. Among the general manifestations are headache, vertigo, vomiting, delirium, convulsions, somnolence or insomnia, mental dulness or excitement; among the local phenomena, palsy, papillitis, papillary changes, venous engorgement, and œdema. When the affection is secondary to contiguous disease it is likely to be infectious and attended with elevation of temperature, perhaps also with chills and sweating. For the simple variety of thrombi, rest, stimulants, and nutrients constitute the best treatment; for the infective variety, operative measures represent the only hopeful therapeutic resource, and to be successful the surgical intervention must be instituted early. In illustration of this last proposition Bacon (*New York Medical Journal*, July 1, 1899) reports three cases of thrombosis of the sigmoid sinus following acute suppurative inflammation of the middle ear, in each of which incision of the sinus and evacuation of the clot in the first stage of the disease were attended with recovery. In this connection the administration of antipyretics is condemned as obscuring the diagnosis. It is pointed out that the detection on bacteriological examination of streptococci and pneumococci in the secretion from the meatus in cases of suppurative inflammation of the middle ear indicates that the inflammation started simultaneously in the middle ear and the attic, and that, therefore, a large incision in the drumhead, extending from below the stapes to the lower portion of the membrana tympani, is desirable, in order to secure the best possible drainage. To overcome the collapse that frequently follows removal of the thrombus, and especially if the internal jugular vein has been tied, in addition to the administration hypodermically of strychnine, whiskey, etc., the infusion of several ounces of decinormal saline solution into the median cephalic vein is considered often imperative.

## News of the Week.

**The New York State Medical Association.**—In the notice of the next annual meeting of this association, published in these columns last week, it was stated that Dr. C. E. Denison was secretary of the association. We should have said secretary of the committee of arrangements. The secretary of the association is Dr. Michael C. O'Brien, 161 West 122d Street, New York City.

**The Plague** continues in Oporto with little change. On September 4th three new cases and one death were reported, the total since the epidemic began being sixty-four cases and twenty-six deaths. The Russian plague commission reports officially that there have been twenty-four cases of the plague in Astrakhan since July 7th, and that the deaths have numbered twenty-three. There is only one case now. In India the outlook is no more encouraging. The governor of Bombay, in the course of a speech a few days ago at Poona, said the plague was spreading, and that, owing to the failure of the monsoon, not only the plague was in the midst of the people, but grim famine was staring at them. He expressed the hope that the September rains would come to their relief, and stated that in the mean time arrangements would be made to open relief routes.

**A New Hospital in New York.**—A certificate of the incorporation of the Emanuel Hospital and Dispensary of New York City was filed a few days ago with the State board of charities for its approval. The particular objects for which the corporation is to be formed are the establishment and maintenance of a hospital or lying-in asylum where persons non-resident can be treated and cared for gratuitously or for a nominal compensation, and also for the establishment of a free dispensary.

**The Intercolonial Medical Congress of Australasia.**—The fifth session of this congress will be held in Brisbane from the 18th to the 23d of September.

**The Medical Society of Nova Scotia.**—At the annual meeting of this society, held in July, the following officers were elected: *President*, Dr. D. McIntosh, of Pugwash; *First Vice-President*, Dr. C. A. Webster, of Yarmouth; *Second Vice-President*, Dr. F. S. Yorston, of Truro; *Secretary-Treasurer*, Dr. W. S. Muir, of Truro.

**Yellow Fever** has been reported from Key West, where, up to September 5th, there have been twenty-eight cases, with three deaths, in the past week. It is a curious commentary on the changed conditions in Havana since the American occupation, that the health

authorities there are considering the advisability of declaring a quarantine against Key West. A case has occurred also at New Orleans, and a death from yellow fever is reported from Vincennes, Ind., the case being that of a man who recently returned from Cuba. In Vera Cruz and other towns along the Mexican coast the fever continues and is attended with an unusual fatality. Reports from Tehuantepec say that nearly all the foreigners arriving there have been taken down with the disease, the mortality being great. The epidemic has, however, notably diminished. This is the first epidemic of fever in this part of Mexico for fifteen years, and the authorities have taken extraordinary measures to prevent its spreading.

**An Army Sanatorium.**—Orders have recently been issued authorizing Surgeon-General Sternberg to establish a sanatorium for the treatment of officers and enlisted men of the army suffering from pulmonary tuberculosis, at Fort Bayard, New Mexico. Hereafter transfers of enlisted men suffering from this disease may be made to this hospital upon the recommendation of medical officers of the army. The surgeon-general is also authorized to provide for the care and treatment of discharged soldiers entitled to the benefits of the United States Soldiers' Home, Washington, D. C., who may be sent to the sanatorium by the board of commissioners of the home.

**Increased Hospital Accommodations in the Philippines.**—Surgeon-General Sternberg has issued orders looking to an increase of the medical department and hospital accommodations at Manila, in conformity with the proposed army of sixty-three thousand men. In view, he says, of the increased army now being sent to the Philippines, and the expectation that active military operations will be resumed, it is evident that the hospital accommodations should be greatly increased. The time required for the construction of a large wooden hospital, however, would be at least six months, so that it will be necessary to depend upon buildings already constructed or upon tent hospitals. Five hundred hospital tents will be sent to Manila at once. The medical department will send two hundred and fifty members of the hospital corps on the *Missouri* and twenty female nurses on the *Relief*. Four surgeons of volunteers with the rank of major are now under orders for Manila, in addition to the commissioned medical officers belonging to the new volunteer regiments.

**The Lane Medical Lectures** for 1900 will be delivered in San Francisco by Sir Michael Foster.

**Gasoline Intoxication.**—A ten-year-old colored boy has been arrested in Philadelphia for the larceny of gasoline from city lamps, for the purpose of inducing intoxication by inhalation. Other cases of the same kind have previously been observed.

**An Epidemic of Dysentery** has broken out at the Pennsylvania State Hospital for the Insane, sixty-six cases and seventeen deaths from this cause having occurred during the month of August. Overcrowding is given as the cause, and new buildings in process of construction are expected to bring relief.

**The Nebraska Way of Lynching.**—They do things scientifically out in Falls City, Neb. A man there, on August 22d, criminally assaulted a little girl, and was quickly arrested and placed in jail; not, however, before a crowd of would-be avengers had tried and failed to get the prisoner away from the officers. Along in the small hours of the morning, several hundred men got together, marched to the jail, broke in the doors, and one of the number—"perhaps a physician," the newspapers have it—"performed a surgical operation which will prevent the prisoner from committing any more such crimes."—*Journal of the American Medical Association.*

**Professor Mosso on Physical Education in America.**—The Rome correspondent of *The Lancet* quotes from a letter of Dr. Angelo Mosso, of Turin, who recently lectured at Clark University, concerning physical education in the United States. "It is enough," he writes, "to look at the passers-by in the American streets to be convinced how much more developed and strong they are than our compatriots. The boys and girls are in point of physique far superior to ours. All the public take interest in physical exercises—every journal being compelled to report athletic competitions, regattas, football encounters, golf matches, and such like, because its readers have even a greater enthusiasm for those topics than for the strife of parties. America teaches us, by the plainest and most impressive of examples, that physical education may be carried to perfection without any military object. In the States no one dreams of becoming a soldier. If military force is required it is provided, as in Great Britain, by voluntary enlistment. Nevertheless, America and the British Isles are precisely the two countries where physical education has reached its highest development."

**The Thirteenth International Medical Congress.**—The preliminary programme of this congress, which will be the largest and most important of the hundred or more congresses officially recognized during the exposition of 1900 has now been issued. The rules of the congress are as follows:

1. The Thirteenth International Medical Congress will be opened in Paris on August 2, 1900, and closed on the 9th of the same month. Its purpose is exclusively scientific.

2. The members of the congress shall consist of doctors of medicine who apply for admission; secondly, men of science who shall be introduced by the French executive committee or by foreign national committees.

3. All members of the congress will receive an admission card after they have paid to the general treasurer of the congress the sum of twenty-five francs ($5). Foreign committees may enrol members of their own nationality.

4. In sending their subscriptions to the treasurer the members of the congress should indicate legibly their names, qualifications, and addresses, and enclose their visiting cards.

5. Apart from other advantages each member of the congress will be entitled to receive a summary of all

the labors of the congress and the printed report of the section to which he belongs.

6. The congress has been divided into twenty-five sections arranged under five principal groups: 1. Biological sciences: Descriptive and comparative anatomy; histology with embryology and teratology; physiology with biological physics and chemistry. 2. Medical sciences: General and experimental pathology; bacteriology and parasites; pathological anatomy; internal pathology; hygiene and medical pathology of children; therapeutics and materia medica; neurology; mental diseases; dermatology and syphilography. 3. Surgical sciences: General surgery; children; urinary surgery; ophthalmology; laryngology; rhinology; otology; stomatology. 4. Obstetrics; gynæcology. 5. Public medicine: Medical jurisprudence; military medicine and surgery; naval medicine; colonial medicine. These sections practically constitute in themselves so many independent congresses, and some, as that on dermatology, are actually existing international societies which meet this time in union with the general medical congress.

7. The executive committee and a general commission of organization are entrusted with the duty of preparing the work of the congress.

8. The congress will sit every day either in general assemblies or in meetings of sections.

9. Two general assemblies will take place, one on the day of the opening of the congress, the other on one of the subsequent days.

10. On the day of the first general assembly the congress will appoint honorary presidents.

11. The general assemblies will be devoted to the delivery of the customary speeches and to the regular votes which have to be recorded. Only such persons as have been designated and invited by the organizing executive committee will be able to speak at the general assemblies.

12. All propositions relating to the labors of the congress must be notified to the executive committee before May 1, 1900. The committee will then decide what course to follow in regard to these proposals.

13. The committee of each section will organize its own programme (the reading of reports, the discussion of the subjects introduced, and the miscellaneous communications).

14. The speeches delivered at the general assemblies and the reports made in the sections will be published in the account given of the labors of the congress. With regard to the miscellaneous communications and discussions, the executive committee reserves the right of examining the same. The time allowed for each communication must not exceed fifteen minutes, and the speakers taking part in the discussion must limit their speeches to five minutes.

15. The written text of the reports, communications, and speeches must be handed over to the secretaries of each section on the day on which they are read or delivered.

16. The French language is the official language of the congress for all the international relations. In the general assemblies, as also in the meetings of the sections, the German, English, and French languages may be employed.

17. All the questions relating to the scientific work of the sections should be submitted to and communicated to the president of the section concerned. For all that relates to the organization and functions of the congress communications should be made to the general secretary of the congress.

18. At the second general assembly of the congress the place of meeting for the following congress shall be designated and the bureau of that congress elected.

The bureau of the congress consists of the president, Dr. Lannelongue, 3, Rue François Ier, Paris; the general secretary, Dr. Chauffard, 21, Rue Saint Guillaume, Paris; and the general treasurer, Dr. Duflocq, 64, Rue Miromesnil, Paris. The executive committee consists of the above three officials, two assistant secretaries (Dr. de Massary and Dr. Léon Weber), and the following eleven committee-men, namely, Drs. Bouchard, Bouilly, Brouardel, Dieu, Gariel, Le Dentu, Malassez, Nocard, Raymond, Rendu, and Roux. The address of the bureau of the congress is 21, Rue de l'École de Médecine, Paris. Then there is a general commission consisting of one hundred and thirty-one Parisian and provincial medical men.

The following members from the United States have sent titles of papers to be read in the various sections: Dr. A. Jacobi, of New York, on "Artificial Lactation and the Use of Sterilized Milk;" Dr. L. D. Bulkley, of New York, on "Syphilis and Associated Infections", Dr. Robert Taylor, of New York, on "The Causes of Generalized Infection in Blennorrhœa"; Dr. John Ashhurst of Philadelphia, on "Radiography in the Study of Fractures and Dislocations"; Dr. Bradford, of Boston, on "Treatment of Pott's Disease (Beginning Phase and Formation of Gibbosity)"; Dr. Christian Fenger, of Chicago, on "Conservative Surgery in Renal Retentions"; Dr. W. White, of Philadelphia, on "Remote Results of Operative Treatment of Prostatic Hypertrophy", Dr. De Schweinitz, of Philadelphia, on "The Comparative Value of Enucleation and Operations Proposed as Substitutes"; Dr. Bosworth, of New York, on "The Pathogeny and Treatment of Suppurative Ethmoiditis"; Dr. Montgomery Baldy of Philadelphia, on "The Surgical Treatment of Cancer of the Uterus", Dr. Lagarde, U. S. A., on "Lesions from Rifle-Balls of Minimum Calibre."

The president of the American committee is Dr. William Osler, of Johns Hopkins University, Baltimore.

**Navy Department,** Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending September 2, 1899. August 25th.—Passed Assistant Surgeon E. R. Stitt detached from the bureau of medicine and surgery, September 25th, and ordered to the *Hartford*. August 28th.—Assistant Surgeon W. M. Garton detached from the *Annapolis*, when placed out of commission, and ordered to the Naval Academy. August 29th.—Assistant Surgeon W. M. Garton, order of August 28th modified, when detached from the *Annapolis*, ordered to the Norfolk navy yard for duty on the *Franklin*, instead of to the Naval Acad-

emy. Pharmacist I. N. Hurd detached from treatment at the naval hospital, Mare Island, Cal., and granted sick leave for three months. August 30th.—Passed Assistant Surgeon J. C. Rosenbleuth detached from the *Nashville* and ordered to the naval hospital, Chelsea, Mass., for treatment. Passed Assistant Surgeon M. S. Guest detached from the Boston navy yard and ordered to the *Wabash*. Assistant Surgeon H. A. Dunn detached from the Washington navy yard, September 2d, and ordered to the Port Royal naval station. Assistant Surgeon A. Stuart detached from the Port Royal naval station, September 2d, and ordered to the *Yankton*. Assistant Surgeon D. B. Kerr detached from the *Yankton* and ordered to the *Marietta* upon reporting of relief. Assistant Surgeon M. K. Johnson detached from the *Marietta* and ordered to the *Nashville*. August 31st.—Pharmacist R. Waggener ordered to the army and navy general hospital, Hot Springs, Ark., for treatment.

**Life Saving in Place of Life Destroying.**—Some time ago the Portuguese residents of Rio de Janeiro subscribed about 500,000 milreis toward the construction of a cruiser for the government of Portugal. The amount was far below what would be needed for building any sort of a war vessel, and Queen Amelia has requested that the money be used to build a sanatorium for indigent consumptives. The suggestion is said not to have been well received by some of the patriotic subscribers to the fund.

**An International Charity Congress.**—Among the multitude of congresses projected for the exposition year in Paris is one to discuss public and private charities. It will be held from July 30th to August 5th, and foreign governments have been requested to send delegates. The subjects for general discussion will be selected by the organization committee, which will also choose the men to open the discussions. Papers on other subjects relating to public assistance and private beneficence will also be read. Authors are requested to send papers to the general secretary three months before the opening of the congress. The congress will be divided into four sections, in which will be discussed charity as relating to—(1) childhood; (2) the sick, the infirm, incurables, the aged; (3) the able-bodied poor; and (4) assistance by furnishing work. Among the subjects suggested to intending contributors of papers are: The working and efficacy of relief at the home; compromise between public and private assistance; treatment and education of children in reform schools, schools of correction, etc.; dispensaries, and other forms of medical charity; assistance to indigent consumptives (measures of relief, whatever the medical treatment may be). The language of the congress will be French. The fee for membership is 20 francs. The attendance of all persons interested in relief work, public or private, is requested.

**Deaths of Centenarians.**—A man named William Gaffney died recently in the Province of Quebec at the alleged age of one hundred and sixteen years. He was born in Ireland and settled in Canada eighty-five years ago. He retained all his faculties up to the day of his death. A patriarch of truly patriarchal age died a few days ago in Alexandria. He was Sophronius, patriarch of the Orthodox Greek Church of Alexandria, Lybia, Ethiopia, and all Egypt. He was the oldest prelate, and probably the oldest priest, of the Christian world, having been born in Constantinople in 1792. He had been a priest for eighty-seven years, a bishop for seventy-eight, archbishop for seventy, and a patriarch for nearly thirty-five years. He is said to have been a man of most striking and venerable appearance, and retained his bodily and intellectual vigor almost to the last moment of his life.

**A Truly Wonderful Performance.**—A telegram from a near-by city, published a few days ago, announced gravely that the eight-months-old child of one of the citizens of the place, "afflicted with complete ossification of the head, was successfully operated on here to-day. From birth the child's head showed no signs of development, and ossification set in, causing partial paralysis. By the operation a portion of the skull was removed. It is believed that the child will recover entirely."

**Obituary Notes.**—Dr. Hamilton Mailly, of Bridgeton, N. J., died August 30th from tuberculosis after a brief illness. He was a native of Delaware, and went to Bridgeton fifteen years ago. He graduated from the medical department of the University of Pennsylvania in 1891. He had been secretary of the Cumberland County Medical Society for several years, and was also at the time of his death a member of the medical staff of the Bridgeton Hospital Association. A widow and one child survive him.—Dr. Cornelius H. Schapps, for many years a practising physician in the Eastern District, and who served for several terms in the Brooklyn board of education, died on September 1st, at his home in Manhattan, where he had lived for the last ten years, since he retired from practice. He was eighty-two years old.—Dr. William H. Caemmerer died at his home in Brooklyn, on August 30th. He was born seventy-eight years ago near Madras, in the East Indies, and was graduated from the University of Jena in 1847. For a number of years he was examining physician at Castle Garden. In 1870 he removed to Brooklyn, and continued his practice up to the time of his last illness. A widow and three children survive him.—Dr. Matthias J. Pennypacker died at Phœnixville, Pa., on August 31st, at the age of seventy-nine years. He was a graduate of the medical department of the University of Pennsylvania. In 1844 he served one term as a member of the Pennsylvania State legislature.—Dr. George S. Polis died at Philadelphia on August 29th, at the age of forty-eight years. He was graduated from the medical department of the University of Pennsylvania in 1876.—Major Augustus A. De Loffre, surgeon in the United States army, died on Sunday at Fort Sam Houston, in San Antonio, Tex. He was a native of France, and was appointed from Louisiana in 1874 to be an assistant surgeon in the army. He attained the rank of major in 1892, and was chief surgeon of the post at San Antonio.

# Reviews and Notices.

A Pocket Dictionary of Hygiene. By C. T. Kingzett, F.I.C., and D. Homfray, B.Sc. London: Baillière, Tindall & Cox. 1898.

This is not strictly a dictionary, but rather a handbook of information on sanitary subjects. The book will be found useful by many of the laity whose knowledge of sanitary matters is limited and who are in need of some elementary instruction on the subject. That the work is apparently written in the interest of the manufacturers of a disinfecting fluid does not impair the value of the information it contains, and which, so far as we have been able to determine by a cursory examination, is reliable.

Handy Book of Medical Progress; a Lexicon of the Recent Advances in Medical Science. By Charles Warrenne Allen, M.D., and Jacob Sobel, M.D. New York: William Wood and Company. 1899.

This is an exceedingly well-chosen title, for the work is essentially a handy book to have on the desk, and in it the physician will find an answer to a host of questions which are constantly coming up before him and concerning which he can find no answer in dictionary or text-book. The definitions of the various titles are somewhat longer than those to be found in the dictionaries, but this is necessitated by the fact that many of the things described are new in principle as well as in application, and therefore demand more than a word in explanation. The new terms of which the meanings are given are chiefly the names of diseases, tests, drugs, and therapeutic methods. Many of them are not strictly new, but there are usually some new facts stated in connection with them. For example, under "Addison's Disease" mention is made of the fact of the occasional occurrence of the disease in children as young as seven days.

A Manual of Surgical Treatment. By W. Watson Cheyne, M.B., F.R.C.S., F.R.S., etc., and F. F. Burghard, M.D. and M.S., F.R.C.S., etc. In six volumes. Vol. I., The Treatment of General Surgical Diseases, including Inflammation, Suppuration, Ulceration, Gangrene, Wounds and their Complications, Infective Diseases, Tumors, and Anæsthetics. Philadelphia and New York: Lea Brothers & Co. 1899.

The first volume of this work gives promise that when the others appear we shall have a useful addition to surgical literature. The subjects treated in this volume are mentioned in the title-page, and in their discussion the authors have not attempted to treat each question exhaustively, recognizing that such effort would be to a great extent unnecessary, but have tried to give what they consider the best and most satisfactory means of accomplishing a given result. An important chapter is that upon anæsthetics, and the advice in it on all points is good, especially that upon the choice of the anæsthetic, but in this country there is very little inclination to use the A.C.E. mixture under any circumstances. The writer of this chapter attributes the immunity among children to bad effects from chloroform, to their greater power of responding to efforts at resuscitation if such are necessary. There is a satisfactory section of the book devoted to wounds and their treatment, but nothing that calls for special mention. In the preparation of the operative field, the authors show a great liking for what they call "strong mixture," which is a mixture of strong carbolic and strong sublimate solution, but for use during the operation they suggest several things which will not be readily accepted in this country. They do not believe that asepsis is either necessary or practicable except under very unusual circumstances, and make antisepsis their working rule. Their recommendation to wash out clean wounds with a 1:2,000 sublimate solution is therefore logical, but, we think that few American surgeons would care to keep a 1:4,000 sublimate solution running continuously, as is suggested, over a healthy joint surface. We can assure the authors that in many places in this country the aseptic method of operating is carried on successfully and conveniently. The infective diseases of wounds have several chapters devoted to them, mostly from the therapeutic point of view, and the last part of the volume is upon "Tumors" which are classified from a clinical and partly pathological point of view, with most of the microscopic characteristics lightly touched upon, and without illustrations, in which the book on the whole is weak. We find much interesting reading in Vol. I., and await its successors. The division into six conveniently made volumes is a happy departure from the heavy single volumes to which we are accustomed in works of this kind.

Traité de Médecine, de MM. Charcot, Bouchard, et Brissaud. Publiée sous la direction de MM. Bouchard, professeur de pathologie générale à la Faculté de médecine de Paris, membre de l'Institut, et Brissaud, professeur agrégé à la Faculté de médecine de Paris, médecin de l'hôpital Saint-Antoine. Vols. I. and II. Paris: Masson et Cie. 1899.

All lovers of good medical literature will welcome the second edition of this excellent system of medicine, appearing within seven years of the first. The editors announce that the work has been entirely revised and enlarged by the addition of much new matter. Volume I. contains articles on bacteria, by M. L. Guignard; general pathology of infection, by A. Charrin; disorders of nutrition, by P. Le Gendre, and infective diseases common to man and animals, by G. H. Roger. The article by Guignard is not intended as a complete treatise on bacteriology, but rather as a general introduction to such a treatise. No attempt is made at a detailed description of all the different forms of bacteria, but only at a presentation—and a most lucid one—of the natural history of microbes in general, of their habitat in and out of the animal body, of polymorphism, attenuation by heat, light, etc., and of the products of these micro-organisms. The second article is a continuation of the first, taking up the effects upon the animal organism of these bacterial products. The article by Le Gendre, in addition to treating of the various disorders of nutrition, such as rickets, osteomalacia, obesity, biliary and renal calculi, diabetes mellitus, gout, etc., contains an interesting discussion of the peculiarly French doctrine of diatheses and dyscrasiæ. The fourth article in the volume is made up of chapters on anthrax, glanders, rabies, tuberculosis, and actinomycosis.

Volume II. contains treatises on typhoid fever, by A. Chantemesse; influenza, dengue, malaria, Asiatic cholera, yellow fever, and plague, by Fernand Widal; typhus fever, by L. H. Thoinot; scarlet fever, measles, German measles, smallpox, vaccina, chickenpox, miliary fever, and mumps, by Louis Guinon; erysipelas, by Emile Boix; diphtheria, by A. Ruault; acute articular rheumatism, by W. Oettinger; and scurvy, by Louis Tollemer. We cannot say so much in praise of this volume as of the first, for the articles are of very varying degrees of merit, and many of them betray the fault, which is unfortunately becoming a characteristic of French medicine, of ignoring the work of foreigners until it has been done over again by a Frenchman. This is peculiarly noticeable in the article on malaria, by Widal. For all that there is new in this treatise it might have been written two years after Laveran's discovery of the plasmodium malariæ. The author of a treatise on malaria published in the year 1899, who says "On ne sait rien de l'habitat extérieure des hématozoaires," proclaims himself ignorant or prejudiced to such a degree as to discredit him everywhere as an authority. It is regrettable that the editors should have admitted an article like this among others of such a superior order.

---

**The Post-Mortem Pulse.**—Dr. H. A. Huntington, of Kingston, Jamaica, offers the suggestion of an artificial pulse to enable students to perform surgical operations on the cadaver under more nearly natural conditions. He writes: "Instead of injecting the arteries as at present, attach a rubber tube to a pump whose force and strokes shall be such as to send a red antiseptic fluid into the arteries of the cadaver, imitating as nearly as possible the conditions in life. Students can then perform all sorts of surgical operations under far more interesting and instructive conditions than on the dead cadaver. Using a gas engine or electric motor with suitable pipes and tubes, every dissecting table can have its 'pulse' ready to 'turn on' to the cadaver."

(Special Report to the MEDICAL RECORD.)

### SECTION OF MEDICINE.

*Second Day—Thursday, August 3d.*

(Concluded from page 351)

**Discussion on Tuberculosis.**—DR. CLIFFORD ALLBUTT, of Cambridge, opened the discussion, treating his subject under the following heads: (1) Modes of infection; (2) morbid anatomy of the first stage; (3) diagnosis of the first stage; (4) prevention; (5) cure, with special reference to sanatorium treatment. In stating his case, the speaker said he was obliged to be a little dogmatic, for which he craved the indulgence of his audience; he then proceeded to say that if tuberculosis was to be cured, it must be in the first stage—that is to say, before it began. In the second stage of the complaint the chance of cure drops fifty per cent. The germ theory of disease was first suggested by the conduct of an old lady who labored under the delusion that the best water for drinking-purposes was to be obtained only from a certain distant pump, to which she was accordingly in the habit of sending for the daily supply used in her house, and when she died from cholera, an isolated case in the district in which she had lived, though numbers had succumbed in the vicinity of her favorite pump, Dr. Snow, a well-known practitioner of the period, became convinced that the germ of the disease had been carried in the water. Catarrh of the apex of the lung was tuberculous, and tuberculosis was "catching." The Italians maintained this for years before English physicians would admit the possibility. However, in common ordinary life it was not catching; it must be communicated in a fairly direct manner from one person to another, for the tubercle bacillus could not long live an independent existence out of the body; it might be cultivated, it is true, but with difficulty. There was evidently, said the professor, a gap here that observers had to fill. Sheep and goats resisted the disease, and it was impossible to communicate it to them, or practically so, but the cow was very susceptible. There is more to be feared from the spray of an expectoration than from the solid sputum itself. Sunlight, fresh air, and cleanliness, personal and in one's surroundings, would expel the microbes, as they did bugs, fleas, and other disagreeable insects. A favorite seat of tuberculosis was the posterior tubular portion of the bronchi. We were constantly inhaling and expelling these bacilli, but when some of them succeeded in fixing themselves in the tubes they soon increased. Tuberculosis was a local disease. "If you do not catch your patient before tuberculosis begins, you have not much chance of curing him." Enclosed tubercle gave no outward and visible sign of its presence, for there was no expectoration. It had, most unfortunately, been authoritatively pronounced, that when there were no tubercle bacilli in the sputum, tuberculosis did not exist; but it often did, and might be recognized by the cog-wheel respiration and the temperature in patients in whom there were no physical signs. If the temperature was taken every two hours during the day, there would be found a tendency for it to run up every now and then to 100° F.

SIR WILLIAM BROADBENT said that there was nothing new in the sanatorium treatment, but constant watching had turned what was guerilla warfare into a regular campaign. If two plans were brought forward, one better than the other, the second-best plan, thoroughly carried out, was preferable to the first when it was carried out in an imperfect manner.

SIR RICHARD DOUGLAS POWELL said he included house-flies among the signs of imperfect sanitation. He thought that sanatoria were of incalculable benefit to poor people whose home surroundings were unsuitable for properly carrying out the necessary treatment. Some digestions could not stand the system of feeding in vogue at the various sanatoria, for plethora would often give rise to hæmoptysis in such cases. One great advantage was the discipline to which patients were obliged to submit, and they learned how to manage themselves. It was not so much the location of a sanatorium that was of primary importance as the way in which it was managed.

DR. OSLER, of Baltimore, laid stress on the importance of an early diagnosis, on examination of the sputum and the respiration; he did not recognize any other physical signs. The examination must be made daily, and sometimes it would be only after the twenty-fifth or thirtieth time that the exact seat of the complaint could be located. The man who ran a sanatorium must be one who could control men. The open-air treatment could be carried out at home, whether out of doors or in a room with a sunny aspect and ever-open windows. Rest, above all, was imperative, and must be complete, of both mind and body.

DR. TYSON, of Philadelphia, looked forward to the time when tuberculosis would be dammed up, but its treatment by medicine must not on any account be wholly ignored. Creosote was a powerful factor in postponing the end.

DR. C. T. WILLIAMS, of London, said there were several hospitals for consumption in London, where from three hundred to four hundred poeple were seen daily, and these patients spat about and the exhalations from them were inhaled by themselves and others in omnibus, tram-car, or railway carriage, so that there ought, one would think, to be a larger mortality from the disease in those districts than elsewhere—but experience proved that this was not by any means the case; on the contrary, the number of victims depended on the density of the population and not on the district. The Strand was the worst in this respect, as the population there amounted to one hundred and forty-one per acre and the mortality from phthisis was $3\frac{1}{3}$ per thousand. In Hackney there were sixty inhabitants to the acre, and the death rate from tuberculosis was 1.43. The speaker agreed with the general tenor of Dr. Allbutt's remarks, and went on to say that it was easy enough to inoculate an animal, but more difficult to know exactly when to take the serum. He thought that tuberculosis could be cured in all its stages, though more readily and successfully in the first. Sanatorium treatment could be carried out in an Englishman's home, he thought, and in some sanatoria it was pushed to extremes; no games were allowed, and patients were not even allowed to read, for fear of their becoming excited.

DR. A. RANSOME thought precaution, as in every case, was better than cure; but the local sanitary authorities stood much in need of educating. They had the power to cause the notification of phthisis, and of abolishing the nests in which lurked the germs of the disease; they could order free bacillary examinations—but too often they did not know how to exercise the powers they possessed in these respects, and stood in immense need of education. The infection lingered in houses, but there was not much fear of contracting it in the open air. Medical men, and especially the British Medical Association, must exert all the influence they possess to move the various sanitary authorities.

Further discussion was adjourned to the following day.

**Carbonic Acid Gas in Heart Disease.**—Dr. W. Ewart then read a paper on "The Treatment of Heart Disease by Inhalations of Carbonic Acid Gas; and on the Uses of the Inhalation in Cardiac Dyspnœa and in Anginoid Pain." He said that mitral stenosis and pain were greatly relieved by the inhalation of carbonic acid gas for thirty seconds, the patient's bowels to be kept very free and the use of cardiac tonics to be restricted; there was not only a relief of pain, but greater freedom of respiration, with an improved state of the pulse and of the appearance generally. Carbonic acid gas acted as an anæsthetic, and also as a stimulus to the muscles of respiration, and a continued use of the inhalations had the effect of gradually removing the dilatation. By the ordinary treatment it was difficult to influence mitral stenosis, but carbonic acid gas always improved and often restored the patient to a condition of comfort. He instanced the case of a man suffering from dilatation of the right side of the heart, cyanotic, and scarcely able to breathe, who in two days showed a marked improvement after inhalations of carbonic acid gas.

Dr. Mitchell Bruce admitted that the treatment referred to by Dr. Ewart was entirely new to him, and thought much credit was due to Dr. Ewart for bringing it forward.

Dr. Barr said that this was also new to him. He saw a good deal of difference between the outward and inward administration of carbonic acid gas, and suggested that a similar result would be attained by strangulation, which was an anæsthetic in about two minutes; then there was morphine, which was, in his opinion, a much more reliable remedy than carbonic acid gas but patients, he said, are whimsical and must be humored. He had known great effects to be attributed to the placing of a clinical thermometer in the axilla. A person suffering from poisoning by carbonic acid gas would be relieved by blood-letting, and he did not think that the presence of carbonic acid gas in the blood would improve a person's color; but, as he remarked before, patients are peculiar, and the inhalation of any mortal thing will sometimes have a good effect on them. Carbonic acid gas might be a remedy, but, in his opinion, that had to be proved.

Dr. C. T. Williams related a case of a person suffering from neurosis of the pulmonary nerve who appeared to be dying, and who suddenly drew in a deep breath and recovered immediately. Possibly this may have been due to the immense accumulation of carbonic acid gas in the blood.

Dr. Wills thought the idea was a good one and certainly deserving of a trial.

Dr. Verco was much pleased with the originality of the idea, and he would be glad to hear that further experience confirmed Dr. Ewart's deductions; for it was a troublesome thing to put carbonic acid gas in a bath, and much simpler for the patient to inhale it. He hoped Dr. Ewart would not be discouraged by the adverse strictures on his treatment.

Dr. Ewart in reply said that he was dealing not with a theory but with facts, which he put forward with confidence.

**The Enlargement of the Chest in Emphysema and Its Treatment.**—Dr. Harry Campbell read a paper on this subject. The enlargement of the chest in emphysema was due, he said, to a shortening of the respiratory muscles in consequence of overaction, in which the sterno-mastoid had no share. This overaction was due to the indrawing, which was excessive, while the expiratory movements were defective. The air was taken into the lungs but not entirely expelled from them; the consequence was that a proper amount of air was not available for the oxygenation of the blood, and the patient should be put under a course of expiratory movements, so as to restore the muscles to their normal condition.

Dr. Ewart was of the opinion that a real shortening of the muscles did take place in such cases, but whether it was a cause or a consequence of the patient's condition he was not prepared to say.

*Third Day—Friday, August 4th.*

**Diagnosis and Treatment of Gastric Ulcer.**—Dr. A. R. Parsons read a paper on this subject. This complication, he said, was often found in conjunction with pneumonia, and was accompanied by pain, vomiting, and collapse. The diagnosis was difficult, and the prognosis depended upon the amount of adjacent mischief.

Dr. Mitchell Bruce said that medicine was losing ground, now that so many interesting complaints were transferred to the domain of the surgeon: for example, gastric ulcer; the diagnosis between perforation and gastric ulcer was of the utmost importance.

Dr. Forbes Ross was understood to say that diagnosis was the result of instinct rather than of skill, but a rapid, thready pulse was characteristic of gastric ulcer, and he had met with a case in which all food taken was passed in a few minutes afterward, sometimes almost directly. The great point, he considered, was to prevent the occurrence of pneumonic complications which supervened sooner or later in the vast majority of cases. Many abscesses at the base of the lung were the remains of gastric ulcers, and when the patient complained of pain in the region of the umbilicus it was diagnostic of pneumonia.

Dr. Calwell related his experience of gastric adhesions as a cause of dyspepsia. These complications might be divided into acute, slight, and intermediate, and were to be met by careful dieting, abdominal support, and, in bad cases, by an exploratory incision.

Dr. Mullick was not aware of the existence of any drug that acted as a specific in cases of gastric ulcer, and thought that a great deal depended on diet, but he would like to know the actual ingredients of the one spoken of by Dr. Calwell. It was usual, he thought, to administer nourishment in such cases per rectum, but if given by the mouth, that usually adopted was beef-tea in small quantities, a teaspoonful or half a teaspoonful at a time—but even that quantity sometimes was found to disagree; much depended on the constitution of the patient, who often aggravated his symptoms by his own injudicious behavior.

Dr. Rolleston related cases that had occurred in his own practice, but they presented no feature of special interest, and he concluded by remarking that gastric ulcer might be confounded with appendicitis.

**Discussion on Tuberculosis.**—Dr. Shingleton Smith, in reopening the discussion on tuberculosis, expressed his opinion that the reasons advanced for the notification of cases of tuberculosis were extremely feeble. He was not an advocate for the treatment of the disease in sanatoria, fashionable though these establishments had become; medical men must not be too hasty in throwing away all that they had learned in order to accept these new-fangled notions. Local patches of tubercle might be treated by excision or injection, but on no account should medical men discard their old-fashioned proved remedies. There was too much that savored of mere business in this sanatorium craze. There was more, much more, to be said about the antitoxin treatment. [Applause.] It was all very well to call out for something fresh: what was wanted was something more and better.

Sir Hugh Beevor spoke about the overcrowded

state of workingmen's dwellings, which were a prolific source of disease and more especially of phthisis. As the poet spoke of some being born great, and of others having greatness thrust upon them, he, in the few remarks he was about to make, would refer only to the unhappy beings who had phthisis thrust upon them. He displayed two diagrams representing the density of population in the various districts of London and their correlation with the prevalence of tuberculosis, which he said would be found applicable to other places besides the metropolis. The overcrowding in all of these was in the main due to the children. It was fortunate that medical men and social reformers did not have to deal with the entire area, and if three thousand more could be supplied with fresh air the problem of London would be solved. There were, however, several levers that might be made available, namely, the desire for fresh air and the desire to prevent tuberculosis.

Dr. Woods Hutchinson, of Buffalo, N. Y., spoke about the diagnosis of tuberculosis and asked, Was there a tuberculous chest?—replying in the affirmative, and further asking if it could be used as a means of diagnosis. What were, he asked, the natural average diameters of the human chest; and was the tuberculous chest flat or round? Popularly it was supposed to be the former, but that was a mistake, for it was really rounder than the normal chest. It appeared to the cursory examiner to be flat, because on a round chest the shoulders were rolled well forward, and if the angles of the scapula projected it was on account of the roundness of the chest. The anthropomorphous apes were beginning, or had begun, to flatten the chest, but in the human fœtus it was perfectly round. The fœtal chest was exactly the quadrupedal chest, and gradually flattened. The tuberculous chest resembled the arrested or undeveloped chest of the monkey, and perhaps that was the reason that tuberculosis was so fearfully prevalent among those animals. The more one could get the shoulders back, the freer would be the play of the lung-bellows.

Dr. Mitchell Bruce felt a repugnance to speaking *ex cathedra*, but he must refer to the prevalence of tuberculosis on board of the training-ships for the royal navy, where eight per thousand died or were invalided every year for phthisis; a number that was altogether out of proportion with the death rate among the aggregate strength of men and boys in the service, where the mortality from all causes was no more than five per thousand, while that of the general population was 2.53 per thousand. Tuberculosis was more than twice as common in an old wooden hulk as it was in a new iron ship, which was no more than might be expected, for sanitation in the former was in the worst possible condition. He would suggest that, if boys must be trained in these wooden vessels, they should be sent to sleep in properly constructed barracks on shore.

Dr. A. R. Parsons thought that there must be a stage in which no tubercle bacilli would be detected, and to diagnose phthisis from slight equivocal physical signs was an impossibility. It was altogether wrong to return such cases as cures; nor was it desirable that they should be congregated with undoubted cases of the disease. He had no faith in creosote, but a great deal in fresh air, sunlight, and suitable diet. Was it necessary to isolate tuberculous patients, or was it possible to accommodate them, say, four in a dormitory?—for if each must have a separate apartment, it would largely increase the cost of building and maintaining a sanatorium.

Dr. Hillier said that the question of the open-air treatment of tuberculosis possessed a special interest for him, for this treatment could be utilized at home instead of sending off unhappy patients to suffer and die at the ends of the earth. He had spent some time in South Africa, and had seen a great many consumptives dumped down there, to die sooner and suffer more than they would have done if they had remained at home. It was customary to recommend a sea voyage in such cases, but there was much to be said for and against such a course. If the patient would go in his own yacht, surrounded by the comforts to which he was accustomed, yes; but a berth on an ocean steamer, down in a stuffy, ill-ventilated cabin? No; such a person would get more harm than good by the voyage. He had seen one case, sent out by a well-known specialist, since dead; the poor wretch came on board in a dying condition and was buried at sea. Specialists would do well to consider a little before they recommended expatriation in advanced cases of tuberculosis. A man in London who keeps his windows open day and night is better off, by far, than a poor wretch smothered on board ship in the tropics. He had visited several of the German sanatoria, and did not consider that it was a matter of climate. He was of opinion that Dr. Williams had given utterance to some very extraordinary remarks, for he had deprecated the circulation among the general public of information on the subject of tuberculosis, on the ground that the dissemination of such knowledge would do more harm than good; and yet he allowed his name to appear associated with that of a society specially founded for the purpose. Tuberculosis was undoubtedly a communicable disease, and was conveyed in the dust of desiccated sputa and by the use of tuberculous food. No harm, but on the contrary much good, would be done by the dissemination of the plain truth, couched in homely language, among the people.

Dr. St. Clair Thomson referred to free tuberculous laryngitis, which was distinguished, first, from general catarrh, and, secondly, from infection and granulation of the vocal cords by the fact that only one cord was affected, whereas both would be implicated in catarrh; the difference was not exactly pathognomonic, but it was highly suggestive. As for the treatment—local, *nil;* general, hygeia, food, and air, but the greatest of these was air.

Dr. Lardner Green read a paper entitled "The Inhalation of Formalin as a Preparation for and Aid to the Open-Air Treatment of Consumption." Formalin, he said, used in a vaporized state cleansed septic wounds. He reported in detail a number of cases in which more benefit was derived from treatment with formalin than from anything the patients had previously used. The combination of formalin and open-air treatment would quickly eradicate consumption or at least make it a perfectly curable disease.

Dr. Newsholme thought that phthisis was certainly communicable, and advocated that persons so affected would derive most benefit from conjoined treatment, as the directions given by two persons were better than that given by one. A prolific source of tuberculosis was to be found in houses with insufficient or defective ventilation. He thought that the power conferred on medical officers of health should be very largely increased. Fifty-six cases of phthisis had been notified to him privately, and no alarm was caused. Each house in which a death occurred was visited and disinfected; while without that private notification the house would, in severe cases, have remained a hotbed of infection. A city subjected to a protracted siege might be compared to a person attacked by phthisis; the earlier relief could be afforded, the less would be the mortality. He strongly suggested to all present the desirability of privately notifying all cases of tuberculosis to the medical officer of health.

Drs. Denton Johns and W. T. Gardner showed a patient who had been treated at their sanatorium. He seemed to be in vigorous health, presenting a great contrast to a photograph of him that had been taken

on his admission. He weighed one hundred and thirty pounds when he entered the sanatorium, and one hundred and seventy-one pounds when he left it. He was said to be the possessor of a cicatrized pulmonic cavity. All the patients took their meals out of doors in all weathers. When asked what the food was, Dr. Johns replied that it consisted of protein compounds equivalent to thirteen pints of milk per diem, and he further said that the patients were carefully weighed every evening; he did not feel satisfied when they did not gain at least three pounds each a day. A lady had gained twenty-three pounds in nine weeks.

Dr. Calwell said that was all very well, but he had heard no explanation of the fact that, whereas one patient did well, another did badly under precisely the same conditions of treatment.

Dr. Burton-Fanning considered it doubtful that sanatorium treatment would be carried on with equally satisfactory results in a private residence. At Nauheim much reliance was placed on absolute rest and quiet. In a sanatorium the patients are under constant supervision, and no complication could set in without being immediately detected.

Dr. Pruen had thought that amusement was useful at first, but in a sanatorium it had been found necessary to avoid everything that had any tendency to cause excitement, even cards sometimes giving rise to a condition that was highly injurious. Life had to be made as monotonous as possible, and patients were told of this before admission. It was possible to cure tuberculosis even in the third stage, but such cases had to be seen three or four times a day.

Dr. R. Burnett, in summing up, said that he thought that the importance of this discussion could not be overestimated. He was also of opinion that medical men had sent far too many patients away to distant countries in the past.

A member thought that certain remarks had been made about another in his absence, and was proceeding to formulate an indictment against the offender, when he was called to order by the chairman, who gave it as his opinion that nothing calling for his interference had been said, and he declared the discussion closed.

---

## SECTION OF OBSTETRICS AND GYNÆCOLOGY.

*Second Day—Thursday, August 3d.*

**The Natural and the Artificial Menopause.**—Mr. Bland Sutton, of London, opened a discussion on "The Natural Menopause Compared with (*a*) the Menopause Produced by Removal of the Uterine Appendages, and (*b*) the Menopause Produced by Removal of the Uterus Without Removal of the Appendages." He said that though we were convinced that the menstrual blood came from the endometrium of the uterine cavity and that the process was controlled by the ovaries, we were absolutely ignorant of its real cause. He had pointed out that the ovaries must be considered to be ductless glands, for morphology taught us that ovulation was not their original or only duty, and they must be included in the same group as the thymus, namely, as temporary glands. Menstruation indicated that the individual was usually mature and nubile. In Great Britain this took place as a rule at the age of fifteen years, though cohabitation was not legal until the age of eighteen years, and marriage was generally later even than that. Menstrual life might be considered to extend over thirty years, from the age of fifteen to forty-five years; the procreative period in a large number of women was only from the age of twenty-five to thirty-five years, or one-third of her menstrual life. Thirty years represented the period during which the ovaries were in full vigor; after the menopause they atrophied and became reduced to one-tenth of their previous weight; this atrophy was due to disappearance of the secreting element, viz., the follicle. If the ovaries were removed menstruation was arrested and other symptoms of the menopause appeared, so that the expression "artificial menopause" was a quite correct one. Leaving a very small portion, even one drachm, of ovarian tissue enabled menstruation to go on. The uterus might be regarded as an incubation chamber for oösperms; it had one other peculiarity besides this, and that was its power of rhythmical change. Modern investigation had proved that the menstrual organ was the endometrium lining the body of the uterus and that alone, but that menstruation depended on the ovaries had been proved by the fact that removal of the ovaries arrested the periodical shedding of the epithelial lining of the endometrium. Loss of blood was only one of the symptoms of menstruation; others were vasomotor changes and increase in the sexual appetite. Normal menopause meant stoppage of the menstruation due to atrophy of the endometrium and of the ovary, and generally came on about the forty-fifth year. It was attended by the following symptoms: flushing, nervousness, mental irritability, and sometimes erotomania. In many women the symptoms gradually subsided and the patient had no further trouble. The simplest way of arresting menstruation was to remove the uterus, and he believed that by that proceeding menstruation was at once and forever arrested. He looked upon the idea of vicarious menstruation as an exploded superstition. Although an abiding amenorrhœa ensued, it was not attended by other symptoms of the menopause. When the ovaries and tubes were entirely removed, flushings resulted, sometimes as often as fifteen in one hour. He had been led to remove the uterus in preference to the removal of ovaries, and in a large number of cases he had found that removal of the uterus did not produce the symptoms he had mentioned. He would like to know what changes took place in the ovary after removal of the uterus. With reference to the relation of the artificial menopause to nubility, if both ovaries had been removed he advised against marriage, but if the uterus only had been removed he thought that marriage might take place if the intending husband was placed in possession of the facts.

Dr. Stuart Nairne, of Glasgow, agreed with Mr. Bland Sutton's conclusions. He had found that there was less shock and a better recovery after removal of the uterus than after taking away the ovaries.

Mr. J. W. Taylor, of Birmingham, had known the menstrual discharge to persist even after complete removal of the uterus by vaginal hysterectomy, and a case was on record in which extra-uterine gestation had been known to occur after that operation. There was no special symptom peculiar to either kind of menopause, and many of the worst cases of nervous symptoms which he had seen were in connection with the natural menopause. When the ovaries were removed in quite young women in whom menstruation had not been long established, the symptoms were slight, and the most severe cases were those which were operated on between the ages of twenty and thirty years. In some of these the symptoms persisted over an interval of many years.

Dr. Malcolm, of London, thought that there was a great difference in the symptoms of the menopause according to the special character of the patient, and that after ovariotomy there was as much difference as in the natural menopause. He doubted whether complete removal of the ovaries always caused cessation of menstruation.

Dr. C. A. L. Reed, of Cincinnati, appreciated the lucid statement of Mr. Bland Sutton on questions which were not by any means settled. He personally

sedulously avoided subjecting patients to the "jolt" of sudden arrest of menstruation, and made a point of leaving some of the ovary, but had sometimes regretted doing so, as a secondary operation had become necessary later on in a few cases. He had paid considerable attention to the changes in the blood which accompany the menopause. The gross manifestation of these changes was the fat formation which took place. The changes in the blood were increase in leucocytes and diminution in hæmoglobin. He had found that there was not much difference in this respect between the natural and the artificial menopause. He had examined only cases of the latter which were due to removal of the appendages.

The President thought that the Fallopian tubes played some part in menstruation, because in the old days of ovariotomy clamp menstruation frequently took place through the stump. He had seen the sexual functions become stronger after removal of the whole uterus and ovaries than they were before, and he had known cases in which menstruation had gone on regularly after complete removal of the ovaries, and had noticed no difference between the normal and artificial menopause.

Mr. Bland Sutton, in reply, said that he would like to have more statistics as to the special tendency to insanity after oöphorectomy. He was surprised to hear the president express his belief in the Fallopian tube being a source of menstrual discharge. He had examined a very large number of Fallopian tubes both in women and monkeys, and had satisfied himself that blood never came from the tubes during menstruation. He believed, in clamp cases when menstrual discharge took place from the stump, that some uterine tissue was included in the clamp. Caution should be exercised in accepting the statements of women with regard to menstruation after operation, and in doubtful cases he made a point of taking the woman into the hospital at about the time of her expected period and watching her for a week or more. He believed that when menstruation followed oöphorectomy a portion of the ovary had always been left behind. That the ovary had other functions than ovulation was proved by the remarkable influence of oöphorectomy on the progress of the disease known as osteo-malacia. The ovary was developed in the same way as the thyroid, the one from the hind-gut and the other from the fore-gut. The secretion of each gland was similar, and they were subject to exactly similar forms of malignant degeneration; they had similarities in structure and in hæmatogenic function.

**The Relationship of Certain Cases of Amenorrhœa to Raynaud's Disease and Subsequent Tuberculosis.**—Professor Byers, of Belfast, read a paper on this subject. His observations were based on four cases; in each local asphyxia was a marked symptom. Raymond taught in 1862 that arrest of menstruation was one of the causes of this disease, but he could find no reference to the connection of Raynaud's disease with tuberculosis, though the latter was present in each of his cases.

**Colporrhaphy.**—Dr. Stuart Nairne, of Glasgow, read a paper describing a new and more complete method of colporrhaphy. The operation consisted in splitting the vagina from the cervix downward on each side, and bringing the sides of the split together on the same principle as Tait's operation for the perineum. A transverse bridge was thus formed on which the cervix rested.

**Prolapse of the Uterus.**—Dr. Inglis Parsons, of London, read a paper on the treatment for prolapse of the uterus. This consisted in injecting quinine sulphate, about 30 ℥ of a twenty-five-per-cent. solution, into each broad ligament, with the object of exciting effusion and so enabling the ligaments to brace up the uterus. The following was the method of performing the injection: The patient was placed in the lithotomy position, usually under anæsthesia. The uterus was held in position by a Playfair probe covered with cotton wool, as that was less likely to perforate the uterus than a sound. Anterior and posterior retractors were used for the vaginal walls, and the injection was then made on each side of the cervix by a modified Pravaz syringe. For a few weeks after injection the patient should be kept at rest and wear a cup-and-stem pessary.

*Third Day—Friday, August 4th.*

**Cœliotomy for Uterine Disease.**—Dr. Macpherson Lawrie, of Weymouth, read a paper entitled "Notes of Fifty Consecutive Cases of Cœliotomy for Diseases of the Uterus and Appendages, with Forty-eight Recoveries, Performed within the Last Twenty Months, with Observations." Of the two deaths in the series, one followed vaginal hysterectomy and the other abdominal hysterectomy for fibroid. In cases of broad-ligament cyst he performed enucleation, subsequently closing the cavity with sutures. As regarded the cases of salpingo-oöphorectomy, when there was no pus in the tubes the symptoms were out of all proportion to the amount of disease present. The condition did not as a rule threaten life, but was very chronic, persisting for many years. He did not operate until after a long trial of palliative measures, and when possible removed the appendages on one side only. He held that in cases under these conditions operation was absolutely justified and necessary. When the uterus was fixed in retroflexion he stitched the fundus to the abdominal wall. In the cases in which pus was present there would be no doubt as to the propriety of operation, and in these cases he always removed the organs on both sides. Oöphorectomy for myoma was not now considered the best treatment. He considered that extra-uterine gestation was always tubal. With respect to cancer of the cervix, he had done vaginal hysterectomy when adhesions were present as long as mobility of the uterus had not entirely disappeared. For small fibroids he preferred vaginal hysterectomy. No objection could be urged against hysterectomy for prolapse when the menopause had passed. Safety after abdominal section depended on asepsis and avoidance of too long operation.

Dr. A. Warden, of Paris, said he had worked with Dr. Doyen for six months. He would remove chronically inflamed appendages by vaginal rather than abdominal section, and thought forceps quite as good as ligature in hysterectomy. Doyen's new clamp forceps exercised a pressure of two thousand kilos on tissue included in its grasp. This was placed on the broad ligament. An erroneous impression had arisen that Doyen trusted to this forceps only; that was not so. He placed a silk ligature in the groove it had formed. During the six months he had been with Doyen he had seen no cases of secondary hemorrhage.

Dr. Tate, of London, had found that in cases of chronic inflammation of appendages more disease was often found on abdominal section than had been anticipated from the bimanual examination. He would not advise vaginal hysterectomy for cancer when there was fixation, but in some cases in which there were one or two bands, which did not, however, prevent the uterus being drawn down, one might operate as a palliative measure. He recalled Professor Martin's dictum that "where the operation was easy it was a good operation, where difficult a bad one."

Mr. J. W. Taylor, of Birmingham, thought the combined operation very good for many cases of fibroid. He did all preliminary work, including separation of the cervix and ligature of the uterine arteries, from the vaginal aspect, with the patient in the lithot-

omy position, and then completed the operation from above. He thought that chronic salpingitis was well treated by vaginal section when operation became necessary, but found that many cases were due to the combined infection of gonorrhœa and syphilis, and these yielded to treatment by potassium iodide and mercury.

**Treatment of Carcinoma of the Uterus.**—Dr. More Madden, of Dublin, read a paper on "Some Methods Employed in the Modern Treatment of the Uterine Cancer." He said that cancer cases formed three per cent. of all the gynæcological cases coming under his care. Of fifty-four cases, forty-seven were found to commence in the cervix; thirty-seven were in multiparæ. As regarded age, between forty and fifty years there were thirty-seven cases, ten above fifty years of age, and eight under forty years. One died of the disease at the age of sixteen years. The diagnosis was made by the careful examination with the microscope of all suspicious conditions of the cervix. When the margins of the os were found to be reddened and shot-like nodules were felt with the finger, and bleeding followed examination, a nodule was excised and examined under the microscope. He advocated early amputation of the cervix uteri. He had performed vaginal hysterectomy in only five of his cases. All the patients recovered from the operation, but only one lived more than two years without recurrence. The results of amputation of the cervix were that there had been no mortality from operation in the whole of his thirty-one cases; in ten cases there was no return in ten years. His method of operating was to transfix the cervix with steel wire, pull it down, and remove it by thermocautery. In non-operable cases he injected methylene blue or absolute alcohol into the growth. He found injections of turpentine relieved the fetor, and for pain he gave morphine.

**Causes of Dystocia.**—Dr. Archdall Reid, of Southsea, read a paper on "The Causes which Render Difficult the Labors of Civilized Women." He thought there was an increasing disproportion between the fœtal head and the pelvis. Forceps was now used six times more frequently than at the beginning of the century. He had attended one thousand cases with three deaths. Ruptured perineum was much more frequent after unassisted labors than when forceps was used. The labors of civilized women were so severe that many would perish if unassisted. Why are the labors of civilized women more difficult than those of savages? Sir James Simpson suggested that education entailed an enlargement of the head which became an hereditary transmission. The doctrine he did not think would bear investigation. His opinion was that even in savage women there was sometimes disproportion, and the result was the loss of both mother and fœtus; among civilized women many or most of these cases would be saved, and so perpetuate the difficulty.

Dr. Purslow, of Birmingham, said that in his opinion the difficulty and delay in the labors of civilized women as compared with savage arose not so much from disproportion of head and pelvis as from weakness of the expulsive muscles. This latter was due to want of their exercise, and probably also to the wearing of corsets. He thought that the squatting position almost always assumed by savage women in parturition had a decided mechanical advantage over the recumbent position assumed by civilized women.

**The Syphilitic Factor in the Diseases of Women.**—Dr. Shaw-Mackenzie, of London, then read a paper on this subject. He urged the more general recognition of syphilis as a cause of disease, especially of cases of menorrhagia accompanied by erosions of the cervix, and had found these cases much improved by treatment with mercury.

**Puerpural Infection.**—Dr. A. Warden, of Paris, read a paper on "The Treatment of Puerperal Infection in the Maternity Hospitals of Paris." He said that serum was largely used, but the results did not justify so far the recognition of any serum as a specific curative agent, and we were yet in ignorance of conditions which should govern the choice of a serum. The treatment of puerperal infection by the Paris accoucheurs was an immediate and routine one. He thought that we ought to consider that the plan of waiting for severe symptoms before commencing treatment was a bad one. There should be prompt recognition of the infected state and prompt local treatment. We recognized infection by rise of pulse and rise of temperature. Pinard advised preventive measures in cases likely to develop infection, such as long labors, placenta prævia, version, etc. Treatment was begun by intra-uterine douche, and if that did not cause a fall of temperature the uterus was curetted, but not before the third day. This was done without chloroform. Vulsella were used, and the curette was a blunt large one. Afterward the uterus was swabbed out and subsequently packed with iodoform gauze. In cases which did not yield to this treatment he would bleed and subsequently perform intravenous transfusion of saline solution, using large quantities.

This concluded the business of the meeting. A vote of thanks to the president was proposed by Dr. Purslow, of Birmingham, seconded by Dr. Shaw Mackenzie, of London, and carried unanimously.

---

## Surgical Suggestions.

**Vaginismus.**—I agree with several writers who say that they have absolutely no results from any plan of treatment other than that which is radically surgical. The various ointments, suppositories, and lotions are useless. Cauterization is also valueless. Rapid and gradual dilatation has been without results in my hands. The treatment should be radical, and consists in total extirpation of the hymen, both posteriorly and anteriorly, if the hymen extends to and is continuous with the urethra. If any considerable portion of the hymen is allowed to remain, all the symptoms may recur. In some instances cure has been secured only by excising the urethral orifice to eradicate every vestige of the hymen.—William A. Edwards.

**Abscess of the Liver: Pathology.**—(1) Abscess of the liver is a micro-organismal disease. (2) The principal factor is a streptococcus. (3) Dysentery is produced by the streptococcus; the amœbæ play no rôle in the pathogenesis of the affection. (4) The point of entrance of the micro-organisms found in the liver is chiefly the intestinal tract, whence they pass to the liver either through the portal blood or the general circulation.—Zancarol.

**Surgical Hints.**—In syphilitic ulcer of the tongue, the floor of the mouth is usually not involved, so that the tongue may be moved quite freely. In epithelioma it becomes involved early, with consequent loss of motion.—If a patient should happen to become salivated during mercurial treatment, do not at once give iodide, since this drug, by increasing the elimination of mercury, will at least temporarily increase the trouble.—Never remove a large sequestrum or a foreign body situated near a blood-vessel of any importance, without being ready to tie the vessel in case of hemorrhage. In one case the carotid artery had to be tied for hemorrhage resulting from the removal of a necrosed portion of the lower jaw.—In urethral stric-

TURE, complete retention may occur even when the stricture is not of a very small calibre. If any inflammation is present, a very slight spasmodic action may suffice to close the canal, and this spasm will continue, and even grow stronger, until a catheter is passed. Always begin with a fair-sized instrument.—IN RETROPHARYNGEAL ABSCESS it used to be advised to empty the abscess first with a trocar, in order to avoid flooding the larynx with pus and causing suffocation. If we can open the abscess with a knife, while the patient's head is lower than his body, in the position adopted for feeding intubation cases, the danger is avoided and the opening will be more thoroughly done.—IN SEVERE PAIN in the testicle occurring in old men, if we can exclude the presence of inflammation due to the ordinary infectious conditions, inquire into the possible presence of gout. In this disease an attack occasionally begins in the testicle, and gives rise to excruciating pain. Colchicum in full doses is a specific for this. Heat is usually grateful to the patient. Cold applications are not indicated.—IN CASES OF STRANGURY occurring in old men, after operations upon the rectum, the condition may sometimes persist for two or more days, especially if there is any prostatic trouble or urethral stricture. This may often be cut short by leaving the catheter in for a few hours. There is no danger in this if our asepsis has been thorough. It is also important to remember that in such cases we may remove only a small part of the urine contained in the bladder. To avoid this percuss the bladder as soon as the urine stops flowing. If we have reason to believe that any urine is left, we should turn the patient over on one side, and we will often see several ounces more gushing out quite fast.—*International Journal of Surgery*, February.

**Legrand's Solution Anæsthésique-Hémostatique** has the following formula:

| | |
|---|---|
| ℞ Gelatin. pur | 2.0 |
| Sodii chloridi | 0.7 |
| Acidi carbol. cryst | 0.1 |
| Eucain. hydrochlor. B | 0.7 |
| Cocain. hydrochlor | 0.3 |
| Aquæ destill ad | 100.0 |

M.

The solution can be sterilized and kept for a long time without deteriorating. The technique of injection is the same as for Schleich's cocaine infiltration anæsthesia. The special value claimed for this solution is the absence of a secondary vasomotor dilatation following the primary vasomotor contraction produced by the cocaine. Gelatin acts as the hæmostatic.

**Abscess of the Liver: Etiology.**—(1) Abscesses of the liver are micro-organismal in origin. (2) They may be monomicrobic or polymicrobic. (3) They develop in the course of diverse affections of the intestinal canal. (4) They are usually pyocholic in origin, rarely pyæmic. (5) They should be opened and drained as soon as recognized.—LOISON AND ARNAUD.

**General Septic Peritonitis.**—Probably as many patients recover from general septic peritonitis by stimulants and purgatives as do by operations. In either event, if it is a case of true general septic peritonitis, the mortality will not be far from ninety-five per cent.—J. M. CARTLEDGE.

**Mammary Carcinoma.**—While I have removed with the breast both pectoral muscles, along with lymphatic glands of the axilla and supraclavicular region, and probably prolonged the life of the patient, such cases should probably be regarded as inoperable, as remote infection has likely already taken place.—H. MCGUIRE.

**Acute Infections of the Gall-Bladder** are very serious; surgical intervention is almost always demanded. Left to themselves, the cases are liable to result in rupture, or even in gangrene, with escape of septic fluid either into the adherent contiguous viscera or into the general peritoneal cavity.—M. H. RICHARDSON.

**Causes of Hernia.**—I have frequently observed in operations for radical cure in adults that the conjoined tendon is unduly narrowed, very thin, or the muscles attached to it are ill-developed. Félizet has described in infants imperfect development of one or both of the pillars of the external ring. The fact should not be lost sight of that the immediate cause of hernia is in a large proportion of cases an increase of the intra-abdominal tension, either persistent or intermittent. This is especially obvious in the hernia of infants. Defective closure of the vaginal process may be present at birth, but a hernia often does not develop because the determining factor is absent. This is supplied in a large proportion of cases by distention of the abdomen with tympanites due to chronic gastro-intestinal catarrh, often associated with rickets; or there may be phimosis with adherent prepuce, vesical calculus, ascarides, prolapsus ani, causing straining during micturition or defecation. It is often noted that the hernia was first observed during an attack of whooping-cough. Ascites is also an important determining cause.—FREDERIC EVE, *The London Lancet*, January 21st.

**To Remove Blood from the Hands.**—When you have blood upon your hands, first wash them in pure water. Using soap at first is a mistake, as soapy water does not dissolve blood rapidly. Clear water and a nail brush should come first, soap next.—*International Journal of Surgery.*

**Section of Stomach.**—At the French Academy, on November 11, 1898, Dr. Périer showed a woman, aged fifty-five years, upon whom a year before he had operated for tumor of the stomach, making an annular excision which left the two cul-de-sacs entirely separated. A double layer of sutures had been introduced and the outer wall had been strengthened by an epiploon covering.—*La Presse Méd.*, November 16, 1898.

**Decinormal Salt Solution.**—Ordinarily, not more than one ounce per minute should be injected into the tissues or vein. Pulmonary œdema, dyspnœa, headache, vertigo, mental excitement, delirium, hallucinations, severe pain in the left side, with engorgement of the liver and spleen, occur from overdistention of the blood-vessels with salt solution.—J. WESLEY BOVEE.

**Tuberculous Peritonitis.**—Laparotomy was performed by Dr. Brault (*Gaz. des Hôpitaux*, No. 80, 1898) on a girl of five years. The surface of the liver was found studded with foci; also the intestines, which were matted together and partly covered with false membrane. The wound was closed without drainage after breaking up adhesions and wiping clean the surface, removing all tuberculous foci. The stitches were removed on the eighth day, and the cure was regarded as perfect.

**Local Anæsthesia.**—Guaiacol in solution in oil is used as a local anæsthetic, especially for the turbinals and for the removal of polypi in the nose and ears. Anæsthesia is obtained in ten minutes. Eucaine, which is less poisonous than cocaine, is used in a solution of five to eight per cent.—LUCAS CHAMPIONNIÈRE.

**A New Method for Extracting Foreign Bodies from the Nasal Fossæ in Children.**—Inject through the sound nostril a current of warm salt water at a

moderate pressure, which, returning by the posterior nares on the occluded side, forces the foreign body out, or at least allows of its being seized with forceps. —Felizet.

**Puerperal Sepsis.**—Four simple things, if universally and carefully used to-day, would very nearly banish puerperal sepsis. They are: (1) The hand scrubbing brush; (2) The bichloride of mercury or equivalent solution for hands and external genitals; (3) The baked (*i.e.*, sterilized) napkin; (4) The clean suit.—George Erety Shoemaker.

**Syphilitic Iritis.**—The chief symptoms are (1) ciliary congestion with a certain amount of pain referred to the forehead or temple, photophobia, and lacrymation; (2) discolored iris, sluggish action of the pupil, which dilates irregularly under atropine; (3) adhesions to the lens, deposit of uveal pigment, nodules of lymph in or on the iris.—Jonathan Hutchinson, Jr.

**Strictures of the Rectum.**—According to the statistics from the large hospitals in London, stricture of the rectum in females is ten times as frequent as in males; hence we can readily see how these strictures would be produced by careless people, particularly the lower classes, who never stop to think when they have a gonorrhœal vaginitis, but use a syringe which infects the rectum.—J. B. Bacon.

**Anthrax.**—Frequent injections of a three-per-cent. carbolic solution about the pustule. Free stimulation, hot applications. It is said that a temperature of 42° C. completely arrests the growth of anthrax bacilli.—Strubell.

**Intracranial Drainage.**—In hydrocephalus it may be considered proven that if permanent drainage can be secured from the ventricles to the subdural space, nature will provide for the absorption of the fluid and prevent recurrence of the ill results of intracranial pressure.—Sutherland and Watson.

**Bernay's Artificial Sponge** (tightly compressed cotton pads) is highly recommended for plugging the anterior or posterior nares by Dr. W. Kelly Simpson. Dr. Antony Roche, of Dublin, recommends for epistaxis, when local pressure and astringents have been tried without success, a very hot linseed poultice to the back of the neck. In many cases the bleeding will stop at once.

**Entero-Vaginal Fistula.**—The danger of fistula in hysterectomy in which clamps and forceps are used leads Schiller to point out the necessity of great care in the application of the latter and the advantage of subsequently protecting their extremities with pledgets of gauze.—*Zeitschrift fur Geb. und Gynäk.*, Bd. xxxviii., Hft. 1.

**Dangers of Nasal Douche.**—Douches should be used only when there is something to remove, as increased secretions and crusts, since disturbance in the sense of smell, headache, and suppuration of the middle ear may be occasioned.—Lichtwitz.

**Tuberculosis.**—It has been the experience of those who see many cases of tuberculosis that creosote should be given with caution or not at all in those patients who have a tendency to hæmoptysis, and in those who have marked febrile movement.—*Ther. Gazette.*

**Keloid.**—These three principles—compression, incision, and electricity—are the most promising means at our command for the treatment of keloid. They should be used separately or in combination.—Shoemaker.

**To Preserve Needles.**—Keep them in a saturated solution of washing soda. Carbolic oils and watery solutions dull all cutting instruments, and in alcohol they will soon rust. Albolene has an unpleasant oiliness but is otherwise good. Calcium chloride in absolute alcohol is efficacious but expensive.—Dawbarn.

**Intratympanic Injections of Hydrogen Peroxide.**—This has been used in obstinate cases of chronic suppuration, without unfavorable result that could be rationally ascribed to it, any more than to the boric acid against which Schwartze and his school have so much inveighed. But when the full-strength solution (three per cent.) of hydrogen peroxide is injected through a small perforation into an acutely inflamed tympanic cavity, we surely put its powers for evil to crucial test.

**Appendicitis.**—However light the clinical expression of appendicitis may be, and how much it may appear to be in favor of a speedy temporary recovery, the operation is always justifiable. As the strength of the infection can never be known with certainty from the beginning, it appears to be wiser to take each appendicitis seriously. Among two evils the smaller should be chosen, and operation is the smaller evil.—Carl Beck.

**Conservative Surgery of the Uterine Appendages.**—The following facts should be borne in mind: (*a*) If the Fallopian tubes are removed, conception is sacrificed; (*b*) if the uterus is removed, menstruation is sacrificed; (*c*) if the ovaries are removed, their secretion is sacrificed. When the ovaries are removed the uterus should always be saved, for the patient will then be free from the unpleasant symptoms which arise when everything is taken out.—Howard A. Kelly.

**To Thread a Needle** hold it with the ring and little fingers of the left hand, instead of with the thumb and forefinger as is the usual way. This method, according to Dr. Joseph M. Jackson, leaves the thumb and forefinger free to grasp the smallest bit of silk or other suture material as it passes through the eye and pull it to a safe distance on the other side. This does away with the slipping back, so common in the old way of changing hands, and incidentally decreases profanity.

**Spinal Caries.**—Open the post-pharyngeal abscess by an incision corresponding to a line of the internal carotid and not through the mouth. In dorsal abscess laminectomy should be performed. Inasmuch as Calot's operation, rhachiclasis, neither deals with the abscess nor guarantees interruption of further progress of the disease, and possesses no advantage over simple laminectomy, but is simply an operation for the forcible reduction of the resulting deformity, it is not viewed with much favor.—Horsley, *British Medical Journal*, October, 1898.

**Oxygen in Wounds.**—Dr. George Stoker (*Medical Press and Circular*, February 8th) relates a number of cases including recent wounds, chronic senile gangrenous ulcer, and lupus, treated by this method. The points suggested in the latter disease are: (1) to remove the diseased surface by scraping. (2) The skin grown under oxygen being almost physiologically perfect is more capable of resisting further pathological attacks than an ordinary cicatrix. (3) The formation of oxidized toxins on the wound itself, and the use of these artificially prepared, not only assist the healing, but also attack outlying lupoid areas, causing them first to break down, afterward to heal, and in this way tend to prevent a later extension of the disease. It is

gratifying to note that these results were attained not only in this case, but also in others of a similar nature.

**Treatment of Wounds.**—The antiseptic method, if contact of strong antiseptics with raw surfaces be avoided, allows an ideal wound healing. In an uninfected wound no drainage is necessary. For the arrest of hemorrhage, torsion should replace ligature in the great majority of cases. Buried catgut sutures are the best for securing apposition of the deeper structures and the skin, for by their use stitch abscesses and the pain and trouble of removing sutures may be avoided. All clean wounds should be left undisturbed for ten days, and should then be healed.—Rutherford Morison.

**Questions for the Woman to Answer.**—When the question is laid before women fairly, whether they had rather retain their organs and have a qualified result from a palliative operation, or lose their organs and be insured immunity from future pelvic inflammatory lesions, some will unhesitatingly choose the former course. There are women who prefer to retain their special organs, suffer occasionally, but yet feel that they are women. There are other women to whom the loss of their organs is worse than death. These, I know, are sentiments difficult for us to appreciate.—W. R. Pryor.

**Total Emasculation for Cancer of the Penis.**—Pantaloni, of Marseilles, reports three instances in the *Archives provinciales de Chirurgie*, November 10, 1898, and reviews the cases previously recorded. It is considered that this is one of the operations for cancer which has given the best results, although this form of epithelioma is less malignant than many of the carcinomas. In one case, that of Chalot, the patient remained cured for three years, and the second patient presented no signs of recurrence at the end of sixteen months. In the author's second observation, the cure already extends over a period of three months. The local results have been satisfactory in almost all instances.

**Spasmodic Torticollis.**—By the use of a spring and clamp of simple construction, made of spring steel similar to that used as trouser fasteners by cyclists, Dr. H. J. Hall (*Medical and Surgical Journal*, August 18, 1898) has cured one patient and relieved a second. A tail-piece runs from the middle of the spring about six inches down the back, so as to keep it in position. A gentle pressure is thus exerted on the back and sides of the neck as far forward as the anterior border of the sterno-mastoid muscles. After a month the spring could in one case be discarded for several hours a day. As a final result there remained slight painless and fixed torticollis due to permanent contraction of the affected muscles, but the patient could turn her head freely and there was no retraction. The second case, of five weeks' duration, was relieved at once, and in three months was practically cured by the clamp and gymnastic exercises.

**Surgical Treatment of Trifacial Neuralgia.**—I think the operation should be done only when the autopsy is performed; in other words, I have never seen more than two permanent successes, and—to be very Hibernian—I doubt very much if they were permanent, because the patients passed away from under my observation within three years. If you should look up the "Index Medicus" and Chipault's French work, you will find that there is an enormous literature upon this subject, from the analysis of which you will perceive that the operation is a very foolish one, except from the point of view of making a surgeon's reputation; and I think almost any remedy, like aconitia and others of the same ilk, will show just as large a number of successes.—Landon Carter Gray.

I have never removed the Gasserian ganglion and never expect to do it. I believe the operation will become obsolete in the near future.—Nicholas Senn.

I have never as yet had occasion to advise the Gasserian-ganglion operation. I have found the medical treatment of the severe trigeminal neuralgia, on lines similar to those advised by Dana, more satisfactory than is often believed, and I have more than once obtained complete relief for a considerable period. In but one case, in fact, have I had to advise an operation, and then I began with a simple excision of the peripheral branch of the nerve. This is not always of permanent benefit, but the period of relief is often very considerable, and I can now recall few cases that have been compelled or been willing to resort to the severer operations back toward the foramina. I hold the removal of the ganglion as the last resort after medical treatment and the lesser operation have failed, and I have not yet been compelled to advise it. As to the pathology, there is certainly in the excised portions of nerve a degeneration. Whether there are also central changes is as yet undetermined.—Philip Coombs Knapp.

I have removed the Gasserian ganglion but once—in a very old lady, and with a fatal result.—W. S. Halsted.

## Correspondence.

### OUR LONDON LETTER.

(From our Special Correspondent.)

PREPARING TO MEET THE PLAGUE—OTOLOGICAL CONGRESS—MAJOR ROSS' EXPEDITION TO SIERRA LEONE—SEAMEN'S HOSPITAL SOCIETY—THE LATE SIR EDWARD FRANKLAND, F.R.S., K.C.B., ETC.—DEATHS IN THE SERVICES.

London, August 18, 1899.

Interest in the Portsmouth meeting is disappearing so rapidly that it will soon be looked upon as "ancient history." Of course those who read papers retain a paternal solicitude in their progeny and the sections in which they were presented, but the march of events brings other things to the front, and who shall stay the flight of time? Certainly not the numerous members who have gone for a holiday, nor the toiling ones who have been unable at present to start.

The arrival of plague in Europe is a cause of considerable apprehension in several countries, and is regarded here as a serious warning. For more than a month various assertions have been made as to the presence of the disease in Oporto. A policy of denial was adopted, but at length the government has been obliged to admit the fact. The delay is unfortunate, and our Portuguese neighbors are naturally excited. The disease has spread to Lisbon and probably to other cities. The secret policy is almost always disastrous. Here we make our preparations, publish the facts, and await the event in confidence. The local government board is awake, and its medical inspectors have already begun a survey of the ports, with a view of strengthening our defences. The medical officers of health of these localities will no doubt be glad of any help or suggestions the inspectors may offer, especially in the smaller ports, for it is there that a stray case is most likely to be introduced. Some of them have a trade with Portugal, and are, of course, not so well equipped for the work as the great fronts. However, the local sanitary authorities of minor ports are too often parsimonious and cannot be persuaded to spend money. Some of them pay their officers of

health a mere trifle, and isolation is unprovided for, and even disinfection accommodation inadequate.

We have had the International Congress of Otology here—the sixth of the series—and a very interesting one it proved. It must also be pronounced a success. For four days, morning and afternoon, sittings were held without exhausting the long list of papers. The museum was the greatest attraction. Professor Politzer voiced this at the last meeting when he said: "Every congress has an outstanding feature. That of this congress has been the museum."

The tropical expedition under Major Ross has arrived safely at its destination, and the colonial governor has promised to do all he can to assist it.

Several well-known men have joined the teaching staff of the London School of Tropical Medicine. So the committee of the Seamen's Hospital Society can laugh at their former staff and repudiate the need of mending their manners. Just as I predicted. It is always so.

Sir Edward Frankland died on the 9th inst. in Norway, where he was taking a holiday. His death was therefore unexpected, and he succumbed after a few days' illness in the seventy-fifth year of his age. He was professor of chemistry at Owen's College from 1851 to 1857; then at St. Bartholomew's Hospital until 1867; at the Royal Institution 1863-67, and the School of Mines 1865-85. He was president of the Chemical Society 1871-72. He was government analyst of the Metropolitan Water Supply, and as such for nearly thirty years responsible for annual reports to the local government board on the condition of that supply. In the course of his long and active career he received many honors from British and foreign societies, among them the fellowship of the Royal Society, of which he became the foreign secretary. Oxford University made him D.C.L. in 1873, and Edinburgh added her LL.D. in 1884. He was also a justice of the peace and received the K.C.B. in 1897. I well remember him in his laboratory during one of the cholera epidemics, surrounded by various specimens for investigating the water and conversing freely on the subject of the disease and its relation to the water supply.

The deaths are also announced of Professor Bunsen, who was a fellow-student of Frankland's, and whose name is deeply engraved on the progress of chemistry during the last half-century; Deputy-Inspector-General William Richardson on the 4th inst.; Brigade Surgeon G. Y. Hunter on the 11th inst., aged sixty-eight years; Surgeon-General J. Alexander W. Thompson in his seventy-eighth year. He retired in 1881 after thirty-seven years' service.

Lieut-Col. C. J. W. Meadows, aged fifty-five years, died on the 2d inst. Surgeon-Major W. C. B. Eatwell died on the 7th, aged eighty years.

## EPIPHORA IN TABES.

To the Editor of the Medical Record.

Sir: In the very comprehensive and able article upon "Epiphora," by Dr. J. H. Woodward, which appeared in the Medical Record of August 12, 1899, I am surprised at his failure to mention the watery eye that is so frequently a symptom of tabes. The article is so comprehensive and methodical in its consideration of epiphora in all its phases, that an omission to mention this not uncommon cause is certainly an oversight. Perhaps I am made rather critical by a quite recent experience, which, in fact, is the duplicate of one of a few years ago—that of a case of beginning tabes, in which a very able oculist had slit up the canaliculi but a few months previously. Knies states that epiphora is a very frequent sympathetic affection of tabes, and Berger claims to have seen it in fully half of his cases. It is usually considered a direct disorder of secretion, but Berger appears to think that it may also be due to an imperfect action of the orbicularis palpebrarum. Knies has observed one case in which obstinate epiphora without objective findings was the initial symptom of tabes. True "crises lacrymales" are occasionally observed. Mendel says that the upper twigs of the facial nerve spring from a separate nucleus in close proximity to that of the oculomotorius. This might explain the reflex excitability of the secretory nerves to the lacrymal apparatus, and thus be an analogue to the facial hyperidrosis sometimes seen in tabes dorsalis.

C. J. Aldrich, M.D.

744 Prospect Street, Cleveland, Ohio.

## URIC ACID IN THE ETIOLOGY OF ANGIO-NEUROTIC ŒDEMA.

To the Editor of the Medical Record.

Sir: In your issue of August 19th appears an article by Dr. Baruch on "Angioneurotic Œdema," in which he says that "the treatment has not so far been very satisfactory." This could hardly be otherwise, for no cause for the condition is certainly known. However, some features in the reports of his cases point both to a cause and to the remedy therefor.

In Case I. the urine showed "numerous uric-acid crystals"; the attacks were invariably in the morning, and seemed to be caused by the use of cold water, but that test proved negative after the morning hours were passed, and the attacks ceased, when the urine was found "neutral in reaction; specific gravity, 1.010; no uric acid."

In Case II. the attacks were also in the morning, but examination of the urine was negative in its results. In Cases III. and IV. the symptoms were severest in the morning, and in both they were preceded by constipation. Nothing is said as to the condition of the urine.

The blood shows its greatest alkalinity during the early morning hours—*i.e.*, before nine o'clock. Hence in people who are of the uric-acid diathesis, more uric acid is then circulating in the blood than at other times. Activity favors its excretion, and the passivity of sleep its retention.

The irritation of uric acid and the alloxuric bodies acts more generally upon the vasoconstrictor fibres, but may also irritate the inhibitory nerves, causing general or local capillary relaxation. In the cases in question we have evidently an angioneurotic irritant, producing local capillary relaxation and exudation, acting in the morning hours.

In Case I. the exciting cause was the application of cold water, but this was inoperative after the morning hours, and after treatment with an alkaline and non-nitrogenous diet; just as would be expected if it was known that the irritant was uric acid. Cold water caused the cutaneous capillaries to fill, but as they were relaxed under the influence of uric acid, œdema occurred, and the extremities naturally were much affected, being farthest from the heart.

In Case II. it is difficult to determine just why the local œdema should have attacked the tongue only, except that such local affection is occasionally the result of the action of uric acid. The "great mental and physical depression and fear of impending death" show a general nervous effect from some unknown cause, and the general similarity of this case to the other three certainly places it in the same class.

In Case III. the application of cold compresses to the swollen penis and scrotum simply aggravated the condition, as did the cold bath in Case I.

In Case IV. the capillary relaxation was more general, involving larger areas of skin and also the gastro-intestinal tract. In both of these cases there was a history of constipation, but that itself may have been caused by uric-acid irritation.

All these cases seemed to show a common cause. In the first the presence of uric acid in the urine and the cure by abstinence from meats and sweets and the use of alkaline drinks declare directly the uric-acid diathesis.

Administration of calomel may be a necessity to relieve an acute attack, but the cure of the condition requires the elimination of uric acid from the system, and such hygiene and diet as will prevent its future accumulation. Sodium phosphate and some of the lithia salts will secure the former. Exercise to increase oxygenation, iron to increase the oxygen-carrying powers of the blood, strychnine for the nerves, together with regulation of the diet—especially of the nitrogenous element—ought to prevent a recurrence of such attacks.

That examination of the urine gives negative results in such cases does not at all disprove the presence of uric acid in the system. It may then be in excess, but temporarily, so to speak, not finding exit through the kidneys, in consequence of some systemic failure, thus producing auto-intoxication.

Numerous tests of the urine for a period extending over several days may be necessary to prove or disprove its excess.

FLORENCE C. BAIER, M.D.

OWATONNA, MINN., August 25, 1899.

## RITUAL CIRCUMCISION.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: The paper on the evils of the ritual practice of circumcision, in a recent number of the MEDICAL RECORD, tends, I believe, to convey a wrong impression to the minds of surgeons unfamiliar with this practice among orthodox Hebrews. Referring to the men who perform this operation, the writer informs us that "they possess neither medical knowledge nor surgical skill; they have no idea as to the existence of germs and understand nothing about the theory of sepsis and antisepsis." Some months ago I was invited to attend an operation performed by one of these practitioners, and being anxious to learn their methods from actual observation, I accepted the invitation.

The operator possessed a case which contained a vial of carbolic acid, iodoform powder, absorbent gauze, absorbent cotton, styptic cotton, and an extremely sharp knife. The penis and adjacent parts were washed, first with water and then with a weak carbolic solution which the operator prepared. The prepuce having been pulled forward, a portion was cut off and the remainder rolled back. The parts were again washed with the carbolic solution, a dressing of iodoform was applied, and the child was put to bed.

The operator did not suck the first blood to stop the hemorrhage, this being a practice which, I believe, has long since been abandoned. He possessed enough surgical knowledge to know how much of the prepuce to remove, and must certainly have known of the existence of germs, because of the cleanliness with which he performed the operation. As to the results obtained, these compare very favorably with those of the surgeon.

In conclusion I wish to state that, though I believe that the operation should in every case be performed by a surgeon, yet I have written the above merely to prove that the evils resulting from the ritual practice are not so great as generally imagined.

MAXWELL BENJAMIN, M.D.

196 ALEXANDER AVENUE.

## New Instruments.

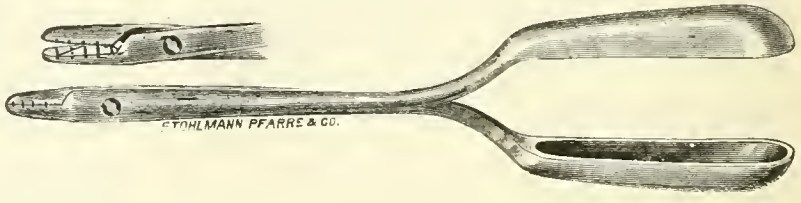
### A STRONG AND SIMPLE NEEDLE FORCEPS WITHOUT A CATCH.

BY W. L. BURRAGE, M.D.,

BOSTON.

THE accompanying cut represents a needle forceps which was made after my design by Messrs. Stohlmann, Pfarre & Co., of New York, about eight years ago, with the addition by the same firm recently of several improvements.

A needle forceps without a catch has several advantages over one with a catch, notably that it takes less time to seize and let go of the needle; there is less twisting of the needle when the grasp is loosened, and without a catch the operator can change his hold, a desirable procedure in driving a long, full curved needle through hard tissues, and whenever by any chance the needle has taken the wrong direction. It is true that it requires more practice to accustom one's self to the use of a catchless forceps, but when the knack is once required it is never lost.



This forceps is simple, consisting of two steel blades joined by a French lock. The handles are hollow to lighten their weight. The jaws are narrow so that they will not break needles, and yet strong so that they will hold firmly and so that they may be used also as shot compressors. There are four horizontal grooves in the jaws of graduated sizes and bevelled at the edges of the jaws so as to hold any size of Hagedorn or full curved needle. The forceps is long and slender, and is therefore especially well adapted to working in the vagina and in the pelvis.

In use the male blade is held by the thumb and forefinger while the female blade swings free (it is essential that the lock should not be tight so as to make the blades work hard on each other). The forefinger is inserted between the handles to open the jaws.

I have used the unmodified forceps in gynecological operating for the past eight years, and have no hesitation in recommending this improved form to those of the profession who want a strong forceps without a catch.

**Cholecystitis.**—In acute cholecystitis of whatever origin, pain is the first, the most important, the most invariable symptom. It is usually severe and paroxysmal. It is situated in the right half of the abdomen, though not always localized in the region of the liver; it may be in the normal situation of the gall bladder; it may be in the epigastrium, or it may be referred directly to the usual seat of the vermiform appendix. In many cases the pain becomes localized in the region of the gall bladder; in a few it persists in areas remote from the liver.—MAURICE RICHARDSON.

## Medical Items.

**Contagious Diseases—Weekly Statement.**—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending September 2, 1899:

| | Cases. | Deaths. |
|---|---|---|
| Tuberculosis | 206 | 151 |
| Typhoid fever | 79 | 12 |
| Scarlet fever | 53 | 4 |
| Measles | 83 | 1 |
| Diphtheria | 104 | 23 |
| Laryngeal diphtheria (croup) | 9 | 6 |
| Cerebro-spinal meningitis | 0 | 14 |
| Chicken-pox | 1 | 0 |

**Congenital Tuberculosis.**—It has been so frequently stated within past years that tuberculosis as a disease is not inherited that cases of manifestly congenital disease demand some notice. At the meeting of the Pathological Society of London, on May 2d last, Professor Macfadyen exhibited part of a tuberculous calf, making the third instance of congenital disease observed by him since 1897, prior to which date he had seen only one example. In the first case since 1897 there was advanced tuberculous disease of the maternal uterus; nothing was known of the condition of the mother in the second; and in the third the lungs were tuberculous, but the uterus was not examined. In the second calf the disease was present in the liver, spleen, lungs, and myocardium, and in the third in the liver, spleen, kidney (to a slight extent), lungs, and the lymphatic glands, hepatic, mesenteric, etc. Calcification was noticed in the second calf. In the adult bovine the lungs, pleura, and peritoneum are usually infected, the spleen rarely.—*English Public Health.*

**Food in Hot Weather.**—The summer weather is upon us with a vengeance as I write, and the difficulties of the housewife in the way of keeping her food supplies pure and wholesome are once more repeating themselves in our seasonal heat period. There is every need to watch this aspect of the food question very closely, for spoiled food is in itself a fertile source of danger. There is another phase of things worthy of our attention at the present time. Food and milk which have been on the verge of spoiling have preservatives added to them by way of keeping them in what is supposed to be an eatable condition. In the case of milk it is to be feared that such "doctored" milk is often added to fresh milk and the mixture sold as the pure article. That no food preservatives can be quite harmless is very generally admitted, but when I read that formalin is actually being employed in restaurants to arrest decomposition in eatables, it is high time a warning should be given that such a practice is a dangerous one. Another caution appropriate for the hot weather is that of warning mothers to see to the purity of the milk on which their infants are fed.—Andrew Wilson in *London News.*

**A Daymare.**—Dr. Tom Robinson, in an article in the *Medical Press and Circular* entitled "Daymare," ends in the following manner: "No one is so selfish as the self-absorbed. Give these patients what name we like, either neurotics, hypochondriacs, or hysterics; say with Shakespeare that 'their flesh is mad,' the fact remains that to us they look for assistance. With disease which has a morbid anatomy we experience but little difficulty, because we to a large extent know the course which the malady will usually run; but these individuals whose whole tissues seem crazy, whose special senses do not appear to see the world as others see it, who, in one word, want common sense—these constitute an enormous bulk of those who appeal to us. What we can do is to listen patiently to their complaints, to examine every organ carefully, and then to speak with absolute frankness. Many of the most gifted men and women which the world has ever seen have had daymare. Martin Luther threw the ink-pot at the devil; Napoleon the first used to say he had heart disease. Sam Johnson was profoundly imaginative. My late gifted teacher, Dr. Sutton, said with so penetrating a truth: 'It really is a grand thing to be nervous; often much unpleasantness and pain are mixed with it, but that is owing to abuse. The world's work is done by the nervous. We may see that the greatest workers are the most nervous, the most sensitive among men.'"

**Injurious Bicycle Saddles.**—The *Sanitary Record* says: "Medical men have not given much attention to the construction of bicycle saddles, but have left the matter to mechanics who know but little of anatomy and physiology. A leading cyclist, who is considered an authority on anything concerning a bicycle, recently displayed his lack of anatomical knowledge by saying: 'When I slip forward in order to keep from bruising my sternum bone on the back of the saddle, my legs go to sleep from lack of circulation of the blood.' He meant that in order to save his coccyx, he slips forward till both ischia drop over in front of the saddle, and allow the edges to press into the sacro-sciatic nerves. It requires anatomical knowledge to design a perfect saddle, and mechanical art to execute the work as designed. The saddle should be too soft to bruise and too firm to give. The best padding is wool felt. Hair is not good because it soon becomes displaced, packs down, and gets hard. The pneumatic pad is not so good as hair because it is too hard when well inflated and when only partly filled presses at one point, allowing the part making the most pressure to come in contact with the hard structure of the saddle. It is also liable to burst or get punctured."

**Inebriety.**—Professor Sims Woodhead, speaking the other day before the Society for the Study of Inebriety in England, came to these conclusions: He held most strongly that a direct transmission of the taste for alcohol never occurred. Of course he accepted very fully the fact that certain nervous diseases and degenerations involving certain altered and weakened inhibitory powers are transmitted from generation to generation. These, however, did not always assume the same form, the manifestation of the effect often taking on very different characters in different generations. But whatever character they assumed, the result as regards alcohol was inevitably the same, and until far more evidence was brought forward than had yet been presented, he should strongly maintain that what was so often spoken of as an inherited taste for alcohol was an inherited weakness and lessened self-restraint affecting many other things besides drink, and that a direct transmission of the taste for alcohol from parents to children in a constitution otherwise healthy did not occur. As with tuberculosis the disease was not transmitted, but only the weakly and unbalanced condition of the tissues.—*The Hospital.*

**Sunshine and Rain in Europe.**—According to a recent report issued by the French Bureau of Agriculture, at 78 Rue de Varennes, Paris, Spain and not Italy should have the adjective "sunny" placed before it On the average it is said Spain enjoys about 3,000 hours of sunshine a year, while Italy has 2,300. France has almost as much sunshine as Italy, her fig-

ures being 2,200. Germany has at her disposal much fewer hours, while England, the land of fogs, has to get along with 1,400, less than half of Spain's amount. The average fall of rain, however, in England is greater than that of any other European country. In the northern part and on the high plateaux of Scotland it is estimated that about 381.25 inches fall each year. In Central England the rainfall averages 234 inches. London is said to have on the average 178 rainy days in the year. Northern Germany has a rainfall of 1,290 mm. In Alsace the rainfall is reckoned at 1,360 mm. Among the Alps St. Bernard receives the greatest rainfall; the annual average register there has been 2,564 mm. In Paris the averages do not go beyond 560 mm., which is about one-tenth of the quantity that falls upon London.—*Sanitarian.*

**Death Rates of Abstainers and Drinkers.**—Of 4,234 deaths collected by the British Medical Association—divided for reference into five classes, namely, (*a*) total abstainers; (*b*) habitually temperate; (*c*) careless drinkers; (*d*) free drinkers; (*e*) habitual drunkards—the ages of death of these in each class were registered, together with the cause, and the average of death for each class computed with the following result: Total abstainers lived on an average 51.22 years. Habitually temperate lived on an average 62.13 years. Careless drinkers lived on an average 59.67 years. Free drinkers lived on an average 57.59 years. Habitual drunkards lived on an average 52.03 years.

**Hygienic Value of Paint.**—Regarding the effect of various paints upon bacteria, Dr. Heimes has recently (*Farben-Zeitung*) delivered a notable lecture before the Greifswald Medical Society. With what kind of paint the walls are covered does not appear to be an unimportant matter for the sanitary conditions in a building. Dr. Heimes conducted the following experiments: He took equally large pieces of oak, poplar, and pine wood, and of iron and cement plates, and covered each with oil paint, size, lime paint, or enamel paint. After the paint had dried perfectly the plates were coated with cultures of various pathogenic bacteria. In this condition the plates were laid in an incubator in which an ordinary room temperature was maintained. From time to time a little was scraped off from the surface of the plates in order to examine them as to the amount of live bacteria present. The result was that upon oil-paint coatings the bacteria were found to die off quicker than on articles coated with other pigments. On enamel paint the bacteria died more slowly, and still slower on lime and size paint. This behavior is probably not due to the chemical properties of the paints, but to their different physical properties, especially to the fact that the liquids containing bacteria dry more slowly or quickly upon the various paints. In consequence of the results of these experiments it is recommended that oil paint only be used in hospitals, schools, barracks, and other buildings where many persons are housed.—*Sanitarian.*

**Health and Doctors.**—By the Federal census of 1870 there were 62,445 physicians and surgeons in the United States. By the census of 1880 the number had increased to 85,671. By the census of 1890 the number was in excess of 100,000, and it is computed from the figures of the various medical associations that the total number by 1900 will be in excess of 125,000, or about double what it was thirty years ago. There were at the date of the last official computation 28,000 physicians and surgeons in the whole of Great Britain, an increase of nearly 6,000 beyond the figures of ten years ago. It is usually computed that the United States, exclusive of newly acquired territory and lands under their protectorate, will show a population of 75,000,000 in 1900, as against 62,000,000 in the census of ten years ago, and if the estimate of the number of physicians and surgeons is correct, the proportion of physicians and surgeons to the whole population would be 1,666 to the million, or a larger proportion than in any other country. These figures seem to indicate that an affirmative answer must be given to the question, Do doctors and health go together? The country in which there are relatively to the whole population the fewest doctors is Russia, in which there are only one-fifth as many as in the United States, though the population of Russia is materially larger. As against 125,000 physicians and surgeons in the United States, there are only 25,000 in Russia, a smaller number than are to be found in Great Britain, though the total population of the Russian Empire, Europe and Asia, was 129,000,000 by the last official census, that of 1897, as against 38,000,000 in Great Britain, and the total area of the Russian Empire is 8,660,000 square miles, as against 120,000 in Great Britain. The death rate in England is low and is constantly getting lower by the adoption of wise sanitary and hygienic measures, but is high and remains high in Russia. There are about 25,000 physicians and surgeons in Germany. There are about 15,000 physician and surgeons in France, 12,000 in Italy, 2,500 in Belgium, 2,000 in Holland, and 6,000 in Spain. Holland, which has a very low death rate, has a larger proportionate number of doctors than any other continental country of Europe, and Norway, in which the conditions are normally favorable to good health, has a small number of doctors and quite a high death rate—the two apparently going together.—*The Sun.*

**Health Reports.**—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended September 1, 1899:

### FLOATING LIVER AND ITS CLINICAL SIGNIFICANCE.*

BY MAX EINHORN, M.D.,

NEW YORK.

THE occurrence of floating liver was first noted upon the dissecting-table by Sauvage,[1] later by Portal,[2] and subsequently demonstrated clinically on living subjects. Cantani[3] was the first to describe a case of floating liver in a woman in 1866. He was followed by other authors who reported isolated cases of this affection, as, for instance, Piatelli,[4] Meissner,[5] Winkler,[6] Sutugin,[7] Chvostek,[8] Wassiliew,[9] E. Smith,[10] Kisbert,[11] and others.

In 1885 Landau[12] published a special monograph entitled, "Floating Liver and Pendulous Abdomen in Women," in which he discussed this subject in an exhaustive and masterly manner. This able clinician called attention to the relative frequency of floating liver, especially in women who had gone through frequent childbirths, and, besides, have a pendulous abdomen. Cases of floating liver in males have also been described, on the whole in comparatively small numbers. Graham[13] has tabulated all cases of floating liver cited in the literature, altogether sixty-eight (inclusive of Landau's fifteen cases). He has also communicated three cases of his own, in one of which the condition was due to an acute luxation of the liver resulting from a trauma, in a young man seventeen years old. As regards sex, fifty-five cases in his table related to women, and thirteen to men.

In 1889, just ten years ago, I[14] presented to the Society of Physicians of the German Hospital and Dispensary (May meeting) a case of floating liver in a man, which was published later in the *New-Yorker Medicinische Monatsschrift*. In again bringing this subject to your attention, I do so, not because I consider floating liver as of rare occurrence, but rather for the reason that I am convinced of its relative frequency; and further, since, when overlooked, it may often give rise to diagnostic errors. You will, perhaps, permit me to present to you the clinical picture of floating liver based upon my own experience, and then return to its significance.

**Definition.**—By the term floating liver (movable liver, hepar migrans, ectopia or luxatio hepatis, hepatoptosis) we designate in general a liver which has fallen downward, and can usually be restored to its normal position, partially or completely, by certain manipulations.

**Etiology.**—The etiology of floating liver has not as yet been entirely elucidated. As in the case of floating kidney, the corset has here also been held responsible, especially by Cruveilhier.[15] It must indeed be conceded that the tight lacing with this modern apparel may exert a detrimental influence upon the position of the abdominal organs; yet floating liver occurs in persons who have never worn a corset. Frequent pregnancies, which often produce pendulous abdomen, have been regarded by Cantani and Winkler as a cause of this condition. This fact, however, although certainly very significant, cannot operate in all cases, for floating liver is also found in virgins and males.

Meissner and Leopold[16] have elaborated a new theory, namely, that occasionally the preformed ligamentum hepatis is elongated in the form of a mesohepar. This is said to furnish the predisposing factor, and upon supervention of other causes, such as pendulous abdomen, lifting and carrying heavy burdens, falls, etc., ectopia hepatis may arise. Landau has never observed a congenital mesohepar in autopsies on children, and considers this theory as strained and not conclusive. According to this author, the factors which are chiefly to be held responsible for the occurrence of floating liver are: (1) Lacerations of the ligamentous structures of the liver (ligamentum coronarium, ligamenta triangularia, and the other peritoneal bands), which may originate through an acute trauma, and much more frequently through repeated ones. (2) An enlargement of the capacity of the abdominal cavity followed by the dislocation of the abdominal and pelvic organs, and indirectly of the liver; for the latter, normally, through the girdle-form support of the abdominal walls, is carried upon the intestines like a cushion; if the intestines slip down, a descent of the liver will then readily take place. Lacerations of the ligaments can occur either through a sudden trauma, such as lifting heavy burdens, falls, etc., or—and this occurs much more frequently—through repeated traumas; among these must be placed sudden and forcible expirations, as in cough, sneezing, and paroxysms of laughing. Thus, Landau described a case of luxation of the liver in a girl twenty-one years old, who, while lifting a piano, experienced suddenly a feeling of tearing in the abdomen. In another case, also in a woman, the patient had had frequent attacks of hay fever and suffered from violent and persisting coryza, with frequent attacks of sneezing. Garnett[17] has also described a case of a sudden development of floating liver, occurring in a woman after exertion. This case is the more important since a rapid cure ensued after five days' rest in bed. I believe likewise that I have observed a case of suddenly appearing floating liver, in a man forty-three years old, after lifting a burden of three hundred pounds. On the following day the patient suffered from slight somnolence and icterus. On examination I found the liver as a prominent tumor beneath the ensiform process, while the area of hepatic dulness on the right half of the thorax was almost entirely absent. As I had never seen the patient before, I could not, of course, say whether dislocation of the liver had not previously existed. As regards the significance of frequent forcible expirations, I observed a case of floating liver in a singer (Abraham S——), and am positively of the opinion that the laborious work of the diaphragm incident to this vocation may lead to laceration of the hepatic ligaments.

The enlargement of the abdominal capacity may result from rapidly progressive emaciation (disappearance of the adipose layer of the omentum, kidneys, etc.), through which more space is left free in the

* Read before the German Medical Society of New York, June 5, 1899.

abdominal cavity, or after childbirths and removal of abdominal tumors. That this factor is of great significance in the occurrence of floating liver, as well as ptosis of the other abdominal organs, is beyond doubt. In most instances, however, this condition, *per se*, is not sufficient to produce floating liver; ordinarily other predisposing factors must co-operate in the development of this affection.

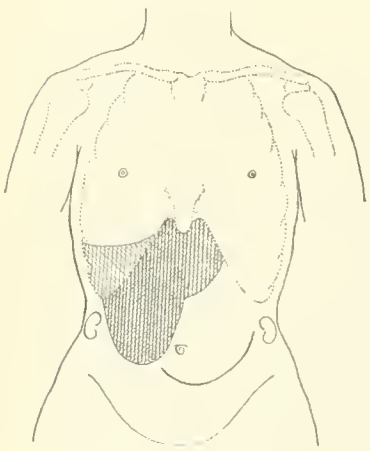

Fig. 1.—Mrs. Sara D——.

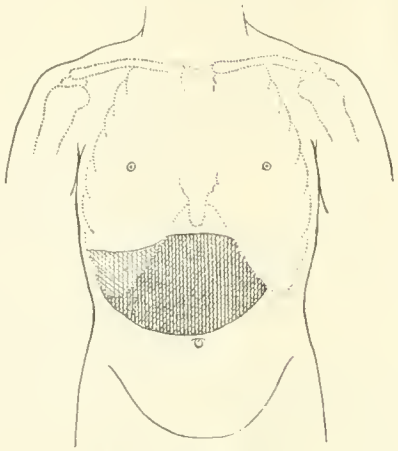

Fig. 2.—Abraham G——.

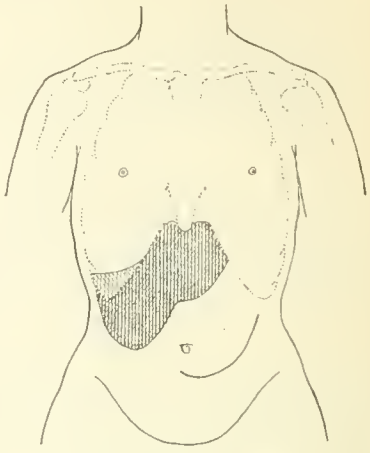

Fig. 3.—Mrs. N. Z——.

Glénard,[18] in much the same manner as Landau, ascribes floating liver to a general splanchnoptosis; that is, he regards it as one of the phenomena of the loosening and gliding down of other abdominal organs.

As regards the frequency of floating liver, Landau stated that he regarded this condition as quite common. In 1887 Glénard observed in thirteen hundred patients fifty-one cases of hepatoptosis, among which thirty-two were complicated with movable kidney, thirty occurring in women and two in men.

In the last ten years, since I have given the subject of dislocation of the liver my attention, I have frequently noted this anomaly; but as I did not accurately examine every patient with reference to this point, the total number of cases observed by me is too small in order to compute the frequency. In the following I will therefore only make use of material which I have had occasion to observe in the last five months of this year (January to May, 1899). All these patients were accurately examined as to the position of the liver as well as of the other abdominal organs, and therefore the acquired figures must be approximately correct. During the period referred to above, I have seen in my private practice eight hundred and four patients (particularly subjects of gastro-intestinal diseases). Among these there were four hundred and thirty-five men and three hundred and sixty-nine women. Of these eight hundred and four patients thirty were cases of floating liver; twenty-one women and nine men. Expressed in percentages the total number of those affected with floating liver would be 3.7 per cent. of all persons suffering from digestive disorders. If we compute the relative frequency of floating liver separately for both sexes we obtain 5.6 per cent. for the female, and two per cent. for the male sex. Among twenty-one women with floating liver, ten also had floating kidney, which was bilateral in three cases. There was no sign of pendulous abdomen in five of the women, while the remaining sixteen had a moderate degree of abdominal flaccidity.

My figures with regard to the frequency of occurrence of floating liver in connection with floating kidney, while resembling those given by Glénard, do not coincide with Landau's views. This author writes as follows: "Inasmuch as movable kidney originates in most instances from the same causes as movable liver, it would appear surprising that these organs are not more commonly found dislocated conjointly than is actually the case. On the other hand, it seems to me that the prolapse of the one organ from the cavity of the thorax is actually the reason why the other aids in filling the space rendered vacant; so that the dislocation of one organ must be considered rather as an obstacle to the dislocation of another. Notwithstanding this, movable liver and movable kidney have been observed simultaneously in four instances, inclusive of one of my own." According to my data, the above conditions of movable liver and movable kidney coexist quite frequently; in female patients in almost one-half of all cases of floating liver. In men, however, this conjoint existence is of rare occurrence.

**Symptomatology.**—Cases of floating liver can be divided into the following five groups:

1. Cases unaccompanied by symptoms, in which the floating liver gives rise to no disturbances.

2. Dyspeptic cases, with indefinite digestive disturbances in conjunction with a feeling of weakness and certain other nervous symptoms.

3. Cases of hepatalgia, in which almost constantly pains are present on the right side of the abdomen (hepatic region), which often radiate toward the back and shoulder blades. These pains frequently subside in the recumbent posture. In many instances sensations of a drawing and tearing character are present.

4. Cases of hepatic colic, in which colicky attacks occur similar to gall-stone colics. In these no icterus is commonly present, although it may appear in rare instances.

5. Asthmatic cases, in which a feeling of fulness and constriction in the upper abdominal region, associated with slight dyspnœa, is especially prominent.

I have often had occasion to observe floating liver without any special symptoms, and such cases are also cited in the literature, as, for instance, the case of Hughes.[19]

In the following I will describe in brief a number of cases, for the purpose of illustrating the four different groups attended with symptoms.

The following cases belong to the dyspeptic group:

Case I.—May, 1899. Mrs. Sarah D——, thirty-seven years old, had gone through seven pregnancies; since a year she had suffered from weakness, loss of appetite, and constipation; had lost much in weight (forty pounds), and lately had been unable to sleep. The patient appeared pale; the abdominal organs were normal. Inspection revealed a slight degree of pendulous abdomen. The area of liver dulness beginning in the right mammary line at the seventh rib extended

from four to five inches below the navel. By means of palpation the liver could be traced downward below the umbilicus. The lower edge could readily be felt and the shape of the liver accurately determined (Fig. 1).* In the recumbent posture the tumor could be readily reduced. The stomach also was markedly displaced, and its curvature extended down to the symphysis. Both kidneys could be readily palpated, and were found movable in the third degree. The patient was directed to wear an abdominal bandage, and to take an abundant diet. After fourteen days she reported that she had increased four pounds in weight, and felt much stronger.

Case II.—May 25, 1899. Abraham G——, fifty years old, has suffered for ten years from varying pains in the chest and in the lower abdominal region. Appetite not good; eructation often present, together with constipation.

Status præsens: Thoracic organs apparently normal. On examination of the patient in the standing posture there is noted a slight protuberance of the upper portion of the abdomen, which is particularly marked somewhat below the ensiform process. Percussion shows that the area of liver dulness in the mammary line commences 1.5 cm. above the border of the ribs; in the median line at the ensiform process, and, perhaps, somewhat lower (0.5 cm.), a clear tympanitic sound is present. From this point to the navel dulness exists. In the recumbent posture the conditions just described remain unaltered. On palpation the entire convex surface of the liver can be readily palpated, and also the lower border of the organ in the umbilical region can be felt (Fig. 2). In the dorsal position the liver can be pushed up to a certain extent, and the area of dulness can then be traced somewhat farther above the right border of the ribs, but the difference, on the whole, is very slight.

Case III.—Floating liver complicated with membranous enteritis. September 25, 1898. Mrs. N. Z——, about forty-four years old, had suffered since early youth from headaches, and now and then from dyspeptic disturbances. For six years obstinate constipation had been present. Periodically the patient is attacked with violent colicky abdominal pains, which are associated with a slight desire for defecation. This is followed by the passage of mucous stools, occasionally of pure mucus, after which diarrhœa occurs for a few days, when the patient feels easier.

Status præsens: Thoracic organs normal; no pendulous abdomen. Liver dulness commences two fingers' breadth above the right border of the ribs. In the recumbent position of the patient the convex surface of the liver can be felt by pressing the hand under the right border of the ribs. Below, the liver fills the entire lumbar region, and its right lobe can be traced down to a point three fingers' breadth below the navel, while the left lobe terminates about two fingers' breadth above the navel (Fig. 3). In attempts to force the liver upward the patient experiences pains, and hence further efforts at reposition were not made. The treatment consisted in the application of an abdominal bandage and the use of oil enemata. The patient was also placed on a liberal diet, and directed to spend much of her time in the open air. She gained considerable in weight, and her disturbances steadily subsided.

The third group of simple hepatic pains (hepatalgias) is well illustrated by the following case:

May 9, 1899. Mrs. E. A. S——, fifty-five years old, had suffered for twelve years from sensitiveness in the epigastrium, and for seven years from constipation and eructations, which were occasionally present. For the past two years pains had appeared in the right lower portion of the abdomen, which persisted almost constantly. Three years ago the patient went through the so-called Saulsbury treatment (a diet consisting of meat and hot water with an addition of zwieback). During this time her weight was reduced from one hundred and twenty-seven to eighty pounds. Later she again increased, and then weighed one hundred and six pounds.

Status præsens: The area of liver dulness begins two fingers' breadth above the right border of the ribs. The liver can be palpated almost a hand's breadth below the navel. The stomach is situated quite low down, extending almost to the pubis; both kidneys are movable, the right in the fourth and the left in the third degree (Fig. 4). The patient was ordered to wear an abdominal bandage, and to take five meals daily. Since then she has felt much better, and the pains on the right side have been much relieved.

The fourth group, the liver colics, is probably the most important, since here erroneous diagnoses are for the most part made. For this reason I have subjoined the histories of several cases:

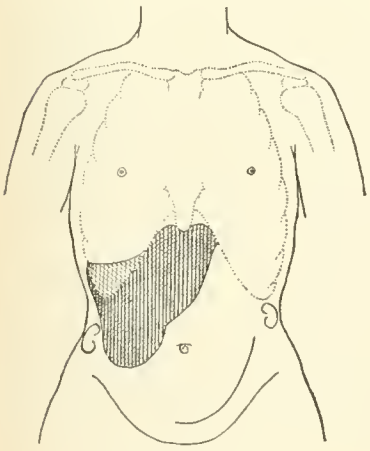

Fig. 4.—Mrs. E. A. S——.

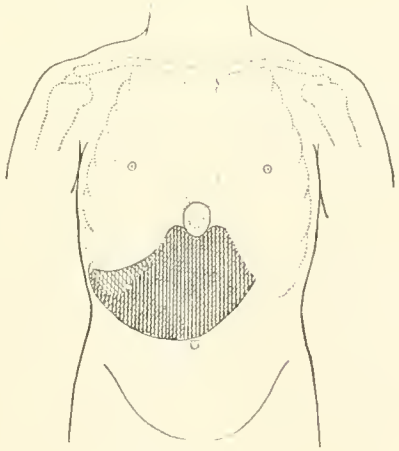

Fig. 5.—David L——.

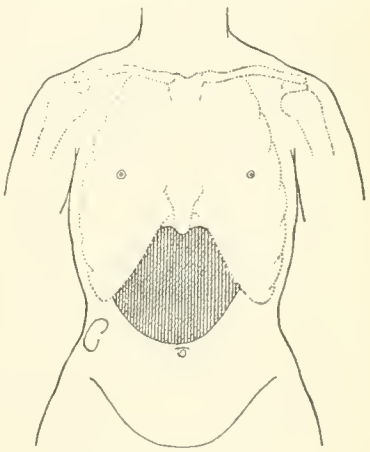

Fig. 6.—Mrs. Minna F——.

Case I.—May 27th. David L——, forty-one years old, had suffered for six weeks from violent pains in the right upper half of the abdomen, of sudden development. The pains were relieved by lying down. Vomiting occasionally appeared during the attacks, of which the patient had five. He was constipated, but had a good appetite; appeared pale and was quite emaciated, but lately had lost much in strength.

* In all the annexed figures, the intensely dark places mark the configuration of the liver accessible to palpation; the slightly darkened, the area of dulness on percussion of this organ. The line drawn below the navel on the left side of the abdomen shows the outline of the greater curvature of the stomach. The kidneys are sketched only if accessible to palpation.

Status præsens: The thoracic organs are intact. In the standing position of the patient inspection reveals that the upper half of the abdomen is occupied by a slight spherical prominence, which extends downward to about a finger's breadth above the navel. On percussion dulness is present in this region, and palpation reveals a tumor with a smooth surface, having the exact shape of the liver (Fig. 5). In the recumbent posture the liver slips back, and then reaches only to a line three fingers' breadth above the navel.

Case II.—April 20, 1899. Mrs. Minna F——, twenty-seven years old, had suffered for seven years at times from violent attacks of gastralgia. These occurred suddenly, and subsided only after injections of morphine. At first the attacks appeared every two or three months; then after the third year an interval of freedom from the attacks took place, which lasted for three years. During the last year the painful paroxysms appeared very frequently; every week, and sometimes more frequently. The appetite and the bowels were normal. The patient had lost twenty-five pounds during the year.

Status præsens: The thoracic organs are normal. The liver is situated low down in the abdomen; the lower margin can be distinctly palpated in the umbilical region: even the incisure can be easily felt (Fig. 6). When the patient lies upon the left side the liver dulness at the right border of the ribs disappears completely. The organ is not enlarged. The right kidney is movable in the fourth degree, but remains in its position when the patient is placed upon the left side. Examination of the stomach contents reveals normal conditions.

Case III.—March 9, 1899. Mrs. L. M. R——, thirty-six years old; had always been in good health; formerly weighed one hundred and sixty pounds. A year ago she was attacked with violent pains in the abdomen (without fever). These were relieved by hot poultices, but nausea occurred and persisted uninterruptedly. The pains in the abdomen recurred frequently in paroxysms; they became more frequent, until lately they have appeared every week. The patient has lost thirty pounds in weight.

Status præsens: The thoracic organs are normal. The area of liver dulness begins in the mammary line, about a finger's breadth above the right border of the ribs, and extends from here into the right lumbar region, almost completely occupying the latter. The left hepatic lobe can likewise be accurately traced; it extends upward to the ensiform process, and downward in the linea alba and to the left of the latter, up to a point about a finger's breadth above the navel (Fig. 7). By palpation the boundaries of the liver as given above could be confirmed. Both kidneys are movable in the fourth degree. The stomach is situated low down and extends with its greater curvature to the symphysis. Pendulous abdomen is not present.

The patient was ordered to wear an abdominal supporter and to live upon substantial diet. She soon began to feel better, and during the last two months increased eight pounds in weight; further attacks also failed to recur.

To the fifth, or asthmatic group, belong the following cases:

Case I.—May, 1899. Abraham S——, twenty-five years old, singer by profession, had suffered for two years from pains in the right upper region of the abdomen, accompanied by a feeling as if he was unable to breathe deeply. The appetite was normal; the bowels were somewhat costive; the patient had had jaundice six months before.

Status præsens: Inspection of the abdomen shows a pronounced protrusion of the upper portion, which extends almost to the navel, and occupies the entire right and part of the left abdominal region. Percussion shows that the area of liver dulness begins only at the border of the ribs in the right mammary line. In the right posterior thoracic region the hepatic dulness is completely absent; in the linea alba the liver dulness can be traced to a line about three fingers' breadth below the navel. By means of palpation the entire liver, the left as well as the right lobe, can be mapped out; almost the entire organ is situated below both borders of the ribs (Fig. 8). In the recumbent posture the liver may be pushed upward by the application of some force, but a complete reduction cannot be made. The urine contains a trace of albumin but no casts; sugar is absent.

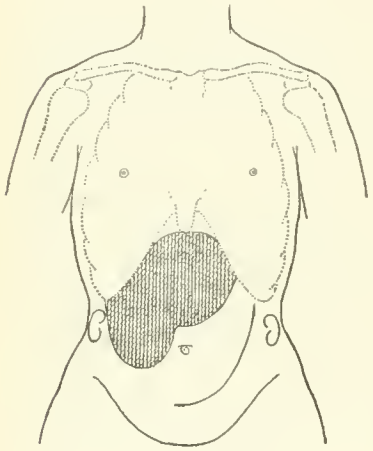

Fig. 7.—Mrs. L. M. R——.

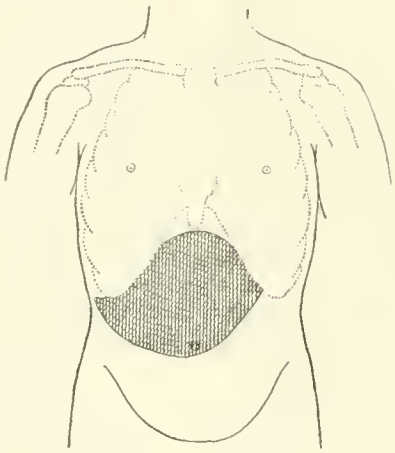

Fig. 8.—Abraham S——.

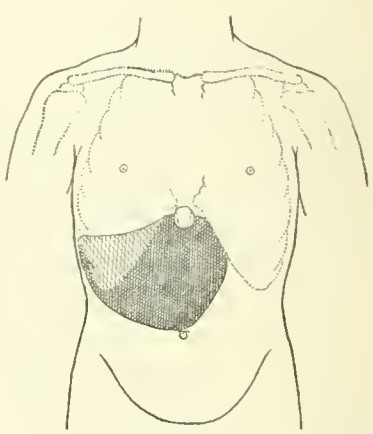

Fig. 9.—Max K——.

Case II.—April 10, 1899. Max K——, forty-seven years old, complains of gastric pains immediately after eating. These consist chiefly in a feeling of fulness. At the same time the patient has a sensation as if he cannot breathe deeply enough. On sitting down or in standing these sensations are quite marked, but on lying down they almost disappear completely. The patient states that he has suffered from these disorders for about two years.

Status præsens: Examination of the lungs and heart fails to reveal anything abnormal. Percussion shows that the area of liver dulness in the right mammary line begins at the margin of the seventh rib and extends almost to the navel. Over the ensiform process tympanitic resonance is found, while farther down distinct dulness is present. Palpation reveals that almost the entire liver can be palpated (Fig. 9). On placing the patient on his left side the liver is displaced considerably toward the left. In the dorsal posture the liver can be pushed upward and toward the right; if

the organ is held firmly in place with the hands, then dulness is present in the thorax.

Of course, cases of floating liver occur in which the symptoms do not correspond exactly to the above-described groups, or in which disturbances exist which belong under two or three groups. What has been said above, however, applies to the majority of cases.

**Diagnosis.**—The diagnosis of floating liver is based upon the demonstration of the fact that this organ has left its normal limits above in the thorax and has been displaced more or less forward and downward. Percussion will show that the upper boundary of the area of liver dulness in the thorax is no longer situated at its normal place, but has been shifted downward. While normally the area of liver dulness begins in the right mammary line at the fifth intercostal space, it is now to be detected at the level of the seventh rib, or at the border of the ribs. Corresponding with this, the zone of dulness at the back of the thorax is also placed more deeply. Occasionally a tympanitic sound is detected over the ensiform process, and this is of special importance since it shows that the intestines or stomach lie above the left lobe of the liver.

Downward from the right margin of the ribs, in the mammary line and extending toward the right from this point, where normally liver dulness terminates, there is found an area of dulness extending downward to the navel, or even to within a few centimetres above the symphysis. In order to determine exactly the upper line of dulness we may percuss from the border of the ribs downward until we meet the tympanitic intestinal resonance; or better still, we may practise percussion from below upward, that is, commencing in the lowermost abdominal region and proceeding in a straight line upward until we discover the dull sound of the liver. It should be remarked, in this connection, that percussion is to be carried out quite delicately, since through forcible tapping the tympanitic resonance of the intestines subjacent to the liver becomes perceptible, and the object of percussion is thus marred.

In the examination of floating liver palpation is of the greatest significance; as in the case of floating kidney it is the most valuable method of examination. By means of palpation alone it is possible in many cases to make a diagnosis of floating liver, although sometimes it must be further elucidated through percussion.

Palpation is here best carried out without the exertion of strong pressure, and by means of the palmar surface of the fingers and often of the entire hand. It is most advantageous to commence the examination closely below the right border of the ribs, and palpating slowly to proceed from here in a downward direction. In cases of floating liver we are always able to find a portion of the liver surface at this place; usually the liver can then be traced downward as far as the navel, or still farther below this point, in the form of a tumor with a smooth surface. Often at the lower margin of resistance the lower liver border, with its incisure, can be accurately palpated. Occasionally by passing the fingers somewhat farther up between the lower border of the ribs and the liver it is possible to discover the convex surface of the liver. In marked cases of ptosis of the liver nearly the entire organ can be palpated both above and below, and the right as well as the left hepatic lobe mapped out exactly.

Palpation, as well as percussion, should be carried out both in the recumbent and upright posture, because in cases of highly developed mobility of the liver the organ sometimes shifts back spontaneously more or less to its normal position when the patient lies down. As regards percussion in the erect position, Harley[20] already recommended this method of examination. In his book on liver diseases it is stated: "In all doubtful cases of 'movable liver' it is therefore necessary also to percuss the organs while the patient is in the erect position. For although cases of atrophy are not rare, cases of abnormally loose suspensory ligaments are common in delicately formed individuals, both male and female."

Palpation also reveals the different degrees of movable liver. These, according to Landau, are as follows:

1. Moderate descent with anteversion or retroversion of the liver.

2. Marked descent: (*a*) With lateral displacement of the liver *in toto* toward the right: (1) With special descent of the right hepatic lobe and raising up of the left; (2) with special descent of the left hepatic lobe and raising up of the right. (*b*) With anteversion or retroversion of the liver.

3. Vertical or oblique displacement of the liver, in which the right lobe usually remains in its normal position, or is displaced toward the right, while the left lobe descends into the abdominal cavity.

Inspection shows in some cases a prominence either of the entire upper abdominal region or a slight protuberance of the abdomen upon the right side. Inspection often contributes toward awakening a suspicion of floating liver, but is never sufficient alone to establish the diagnosis.

The condition of mobility of the liver is investigated in a recumbent posture of the patient. After having practised palpation we attempt by means of pressure upon the abdominal walls with one hand, or, in case of large size of the liver, with both hands, to move the organ in a direction from below and behind, upward and forward. If a complete or partial reposition is possible, and the liver is retained in its new position by an assistant or by the patient himself, the line of dulness at the right side of the chest is found to have been shifted upward. As a matter of fact, reposition cannot be carried out in all cases of floating liver. Occasionally the mobility of the organ from the right toward the left, and *vice versa* from the left to the right, can be demonstrated, while its displacement upward meets with difficulties, especially in patients with tense abdominal walls.

**Differential Diagnosis.**—To make a positive diagnosis of genuine floating liver, it is not sufficient to determine that the organ has left its normal position, but it must also be shown that no diseases of the intrathoracic organs has caused a filling up of the thoracic cavity, and thus has given rise to a downward displacement of the liver. This is, of course, very easy, since such processes (pleuritic exudations, subphrenic abscess, etc.), if developed in a high degree, can be recognized without difficulty. On the other hand, if not marked, they do not lead to descent of the liver.

Enlargement of the liver or hepatic tumors, aside from their peculiar shape, are in general recognized by the fact that the liver is to be found in its normal position (as shown by percussion of the thorax) and that these tumors directly merge in the organ. Errors in the diagnosis of floating liver in cases in which other tumors are present, have often been made, as, for example the case of W. Legg.[21] On the other hand, floating liver has been frequently mistaken for a renal tumor or hydronephrosis; thus, for instance, Smith has described a case in which during life floating kidney had been diagnosticated, while at the autopsy a floating liver was found. Peters[22] has published a case in which he operated for hydronephrosis, but found a prolapsed liver, the kidney being healthy and in its normal place. Mundé[23] reports a case of floating liver which was diagnosticated as floating kidney.

These mistakes will, however, rarely or never occur with thorough methods of examination. A constricted liver will scarcely ever be mistaken for floating liver,

since in the former the liver is situated in its normal place, and only part of it is found farther downward.

**Treatment.**—The treatment of floating liver resembles, on the whole, that of enteroptosis, and especially that of floating kidney. Here, also, the chief measure is the application of well-fitting abdominal bandages, which support the lower half of the abdomen in an upward direction and increase the tension of the abdominal walls. A special pad for pressing the liver still farther back is of as little service here as in floating kidney. Aside from this, so to speak, orthopædic treatment of the abdomen, other physical and dietetic means must be considered. General massage, and hydrotherapeutic measures which have for their aim the strengthening of the organism, are of high value. In the front rank of all these methods is an appropriate diet. In most weakly individuals an abundant diet (or rather forced feeding) must be prescribed. The patient should be directed to take as much food as other healthy persons, and a little more. If, besides the ordinary diet, an additional quarter of a pound of butter is ordered daily, much will be accomplished by this means alone, and most of the patients will soon show an increase in weight. On the other hand, persons who are heavy eaters and rather inclined to corpulency should reduce the amount of food within proper limits.

Gymnastic exercises in the open air, and, in cases with a tendency to constipation, special exercises for the abdominal muscles, are likewise of value. Occasionally, particularly when the gastric and intestinal symptoms are strongly pronounced, these must be treated according to the commonly accepted rules.

In surgical practice the attempt has been made to remove the disease by suturing the liver to the abdominal walls. Such operations have been performed by Billroth,[24] Tscherning,[25] Marchant,[26] and Richelot.[27] It seems, however, that these operations have never attained any popularity, and probably will not come into general use. As already remarked above, we know indeed that floating liver is commonly one of the phenomena of enteroptosis, and that through an operation (hepatopexy) the original trouble is not removed. Here also, as in the case of floating kidney,[28] I am completely in favor of medicinal treatment, that is, mechanical and dietetic, and am opposed to operative procedures.

Having almost exhausted the subject of floating liver, permit me to say a few words regarding the clinical significance of this affection. From the figures cited by me above it appears that this affection is not of such rare occurrence. Every physician now and then will have occasion to discover cases of floating liver by means of accurate examination, and should therefore give this disease his attention. In the second place, recognition of floating liver is of special importance, since otherwise errors in diagnosis may be made which may prove detrimental.

In the last two years I have met in my own practice with four cases of floating liver, in which well-known physicians in New York and Philadelphia had been led to make errors in diagnosis. In three cases of floating liver in women, the diagnosis of gastric cancer had been made owing to the presence of a tumor situated below the right border of the ribs, and extending toward the left. In one case of floating liver in a man, the diagnosis of appendicitis had been made by one physician and of gall stones by another; and both advised urgent resort to operative treatment. The patient, however, soon recovered after the application of a simple abdominal bandage.

The group of cases of floating liver with hepatic colic is often confounded with cholelithiasis. I have certainly observed five cases of this kind in which erroneous diagnoses had been made. One of these cases I reported about six years ago to the Society of Physicians of the German Hospital and Dispensary of this city. The subject was a man, sixty years old, who for ten years had frequently suffered with violent colicky pains in the region of the liver, so that injections of morphine had always to be administered for the relief of the attacks. The patient had gone through all the various gall-stone cures, but without the least improvement. Operative procedures had therefore been advised by almost every one of the medical men whom he had consulted. The patient, however, objected to an operation, and in the course of his wanderings happened to come to me. I detected a typical floating liver, and ordered the patient to wear a well-fitting abdominal bandage, and since that time he has had no further attacks, and has enjoyed perfect health.

I cannot, therefore, urge too strongly the diagnostic importance of floating liver, and would further remark that appropriate treatment of this affection is crowned with the most brilliant success in the majority of cases.

## THE PRACTICAL TREATMENT OF TYPHOID FEVER.[1]

By BASIL M. TAYLOR, M.D.,
GREENSBURG, KY.

You will pardon me if I ask your indulgence for presenting a paper on a subject that has been written threadbare in every medical society. Few, indeed, are the programmes that have no paper upon this disease. Though discussed by us all, still we have only approached the land, anchored in a small inlet, and picked up a few pebbles along the beach of knowledge of typhoid fever. This is a disease that we all meet, and it claims its victims of all ages, from the cradle to old age, the weak and the strong, the rich and the poor. I will not burden you with text-book theories or temperature charts—these you can get at your leisure—but will give you facts as they have come from original research. Neither will I discuss pathology—it is the patient and not the disease that demands our attention.

As typhoid fever is a self-limited disease, we cannot abort or even cure. Those cases that are aborted are not typhoid fever. We are only nature's assistant, or else we are *particeps criminis*. In our treatment of diseases we occupy one of two places—we either aid the patient or the disease. There is no neutral ground unless it is outside the patient's house. Gentlemen, when you weigh this statement carefully you will find it the truth. Every dose of medicine requires some antagonism. When the body is at war with disease, struggling for the survival of the fittest, every dose the patient takes necessarily occupies the attention of the organs of elimination. Toxins and medicines alike pass out together. Then, if our remedy is an irritant, upon which side do we stand? An enemy under false colors? These organs will quickly give you the alarm if you are firing at your own men. Pills and bullets are blind, and therefore wound friend and foe alike. The coma vigil, wild delirium, thready pulse, revolting stomach, all point with unerring finger to the mistakes in doses and diet. When the poor, miserable patient has the disease and the doctor both to fight, he deserves promotion if he survives the desperate attempts of both to kill. You may think this a little harsh, but when you recall the lingering cases of typhoid fever on your list, you may well say that ninety per cent. could have been different. I do not mean those cases in which Bright's disease or some chronic trouble already has a foreclosed mortgage on the patient, but those cases that began with typhoid fever.

The course and duration of a case of typhoid fever depend upon the physiology and pathology of the patient, and our conduct.

We all have the title of doctor of medicine, but in typhoid fever we are not doctors but judges. We hold the same relation to the disease and patient as his honor does to defendant and plaintiff. We are not called upon to give medicine because we have that privilege, but to sit at the bedside and judge, as it were, the issues as they are presented; in fact, to keep out factions and party jealousies among the organs and to bring the case to trial between germs and patient. Gentlemen, this means more than using the thermometer, feeling the pulse, or looking at the tongue. It means more than using text-books as our compass. Each day of the disease is a day unto itself. The disease is divided into stages of weeks, but we must divide it into stages of days. Each day gives you light upon that day only.

One has wisely said, "The proper study of mankind is man." To be successful, then, "know your patient"; unless you do, he will not know himself long.

When called to a case of typhoid fever at any stage, open the journal and examine carefully the liabilities and assets. Like love, that levels all ranks and hides a multitude of faults, there is one word in our language that covers all knowledge, though it be always hid. This word is "why." It is the alpha and omega in all consultations. It is a question that I ask myself about every symptom. At every bedside I am always twins and we hold a consultation. Is the patient older than his age? If so, why? Is he anæmic or plethoric? If so, why? Is his temperature too high? If so, why? Is his pulse too strong, too weak, or too quick? If so, why? Is he nervous, full of pains and aches? If so, why? Is his tongue foul, are his sweats acid, his bowels too active? If so, why? There is no necessity for foul tongues, delirium, acid sweats, pains, headaches, sick stomachs, insomnia, high temperature, and weak pulses in typhoid fever. If we will practise physiology instead of medicine, we will avoid these.

The sum total then, gentlemen, is, when you get a typhoid-fever patient in bed, give him a rest; I mean, a rest from the crown of his head to the soles of his feet. There will be a drain on the system, a disturbance of the equilibrium between assimilation and waste. The patient lives on himself to a certain degree. Then it is that we must minimize waste in any organ. When one is financially embarrassed, he must cut off unnecessary expenses if he expects to be established. The same rule applies to us physically.

The patient's mind must not be upon his business. If he has been irregular in his habits, we must at once establish a regularity. In fact, we must as nearly as possible re-establish his organic harmony and let each organ do its work. I don't mean that it is possible to anoint a man with clay or by a simple touch of the hand work a miracle and give him a new set of organs; but I mean, if a man has been poisoning himself or has been irregular in habits, we can withdraw the poison or make regular his habits, and thus help the cause.

In seven years' experience with typhoid I have lost few patients. Four deaths occurred from hemorrhages caused by ignorant nurses meddling with the cases—either giving purgatives or bad feeding. The fifth case was complicated by inflammatory rheumatism. I have never had any bad results; the patients always got well without after trouble, so common in fevers.

I have given you a few general principles preliminary to the treatment of a case of fever. I will now enter into the treatment in detail. When I say in detail, I do not mean the treatment of typhoid fever in general, but the treatment of the patient. To give the general outlines for treatment would contradict my statement that I would not give you text-book theories which are treatment in general for typhoid fever.

Let us divide our cases into two classes—those who were healthy prior to the acute disease, and those who have had chronic diseases for years. In the first class we are at an advantage, and in the second we are laboring under great difficulties, and it requires sound judgment to keep on the right side.

[1] Read before the Kentucky State Medical Society, at Louisville, May 19, 1899.

Case A is in the first class. He is a young man of twenty and a perfect type of physical manhood. He has been complaining for a week and has called at the doctor's office several times for medicine. Once or twice the doctor found him with a degree or two of fever. He was given calomel for biliousness and quinine for possible malaria, or something for the young man to take. He gradually grows worse, and after having a restless night with headache and general pains, he sends for the doctor. Right here, gentlemen, is a chance for brilliant success or a fatal and criminal mistake. He has a temperature, perhaps, of 103° F. He has had a hard chill. His pulse is rapid but regular and of good volume. Now, for your question why? The functions of the stomach are threefold—the Trinity, as it were. They are digestive, absorbing, and germicidal. To impair one necessarily impairs the other two. Here is the keynote to the whole matter—keep in harmony with the Trinity. To reject one part is to reject the others as well. The patient has taken medicine irritating to the stomach and has been eating indiscriminately since the first symptoms of his trouble, and the chill, high fever, and headaches tell us of the fact. Now, gentlemen, allow me to use here a theory for reference: "Give liquid nourishment and stimulants." Right here is where we are deceived—stimulants—a dangerous weapon, indeed! He is given another purgative, more quinine, and he is directed to take a glass of milk every three hours, and a tablespoonful of whiskey or brandy every four hours until you return. Have any of you ever been guilty of this mistake? Think of it! I repeat it: A "glass of milk every three hours, and a tablespoonful of whiskey every four hours until you return!"

Well, you may ask, "What of it? I can show authority for such directions!" So can I show where the Jews crucified their Saviour, too. A stomach when in perfect health cannot digest food long oftener than three times a day. But when the healthy stomach of Case A takes typhoid fever, and, repeating my words, it needs a rest for the long task it has before it, you cause it to work constantly by giving food every three hours. What does this do? It breaks the link in the Trinity by hindering digestion, and, of course, hinders secretion and the germicidal power of the stomach. This is kept up for a week or more until the patient begins to vomit. His temperature is running to 104° or 105° F. His expression is dull and he is delirious. His pulse is growing weaker, and you are increasing your stimulants. What is the matter, and what, in the name of Heaven, are you doing? Take an old expression: "When the cat's away, the mice will play." When digestive and germicidal functions are crippled, germs take charge of the glasses of milk and the patient poisons himself hourly. Each glass of milk gives impetus to the trouble. No wonder it takes him weeks and months to recover. The disease and the doctor make a combination disastrous to any patient, though he be made of steel. This is where the dull characteristic expression, the delirium, the tympanites, the gurgling in the right iliac fossa, the feeble pulse, the emanation, the aches and pains, the diarrhœa come from. The text-books tell you how to diagnose a case of fever from the above symptoms. Is it possible that we must get a patient into the above condition before we can safely say he has typhoid fever? I am proud to say you will find the above symptoms lacking in my cases. The bright face, clean tongue, smooth skin, regular bowels, no pain, no delirium, no vomiting, a pulse that is scarcely above normal, a low temperature, peaceful sleep at night, a general good feeling, all tell a tale that gives me a different picture from the one I have just given you.

Now, about the whiskey you have been giving. Here is another criminal mistake. Why? Because the pulse laboring under the poison from overfeeding is accelerated. You mistake this for an indication for stimulation. If any of you ride a bicycle, or ever walk up a hill, you know that the best way to reach the top with little exertion is to walk or ride as slowly as possible, and thus save your energy. But, upon the other hand, if you start from the bottom in a run, and increase as you go up the hill, you will find yourself exhausted and unable to go further. So it is with the heart in disease. It needs rest instead of stimulation to over-exertion. This causes heart failure and cannot but result disastrously. Let the heart alone. It knows its own business better than we do. Never, never, under any circumstances try to stimulate a weak heart muscle. It causes only exhaustion. I have told you what you ought not to do, so I will now give you my treatment of case A.

The first thing I never give is a purgative. Why? Because there already exists an inflammation in the bowel and it is unsurgical to cause severe muscular action over any inflamed area. Calomel in this case, then, is unsurgical, if you please. Some may argue that bile is an antiseptic. Then, if it is, the jaundiced only would have typhoid fever. Bile can do nothing with the typhoid-fever bacilli that are already in Peyer's glands. These are the ones that concern us.

If the patient is nauseated, I withdraw all food for twelve or twenty-four hours. Then I feed him three times a day; not every three hours. If he is not hungry at the meal time, I direct him to wait till he has an appetite. This waiting will not occur very often. His food consists of beef tea, beefsteak scraped into a pulp or run twice through a meat chopper, crackers rolled fine, eggs either raw or cooked lightly, and soups in small quantities. The food is in small quantities and highly nutritious. Solid food I know is against the advice of every authority. But let us look into digestion. Does beefsteak pass out of the stomach a solid or liquid? Do eggs, milk, crackers pass out as solids or liquids? Milk, the great fever killer, and the only reliable food some advise, always becomes a solid after it enters the stomach. So where is the difference? Solid food is not dangerous if it is taken in a condition and in a quantity that the stomach will digest. Never allow your patient to eat anything that he is required to masticate, but always prepare meat and other food, so that it needs only to be mixed with the saliva. Then his stomach will digest perfectly the food and the patient will be nourished and the germs starved, and his stomach will get the needed rest, and then there will be no self-poisoning from decomposed food that passes out of his stomach every three hours—food rotten enough to kill a well man.

Orange or lemon juice at intervals will be grateful to the patient, and will do no harm. If there is no fermentation, the patient may take gelatin with rich cream over it. This gelatin and cream should be given in small quantities and on an empty stomach. Let all food be highly nutritious and small in bulk and easily digested—food that will leave the stomach in proper time and will not over-stimulate gastric secretions.

When the temperature runs over 101° F., I use as an antipyretic antifebrin. I usually give three doses during the day and one at night if the patient is at all restless. As a rule, I give medicine for its effect on the patient and not on his friends. I do not give medicine until I see a dose is indicated. Some may want medicine because they are sick; and if they persist in it, I quote one of Solomon's proverbs to them. Solomon was a very good physician. The one to which I refer is: "He who meddleth with strife is like one that taketh a dog by the ears." The entire

organism has all it can attend to without our throwing any straws in the way by giving useless remedies. If the patient is a little restless for a few nights, I give him a sedative. I like bromidia very well because it has no bad after-effects. As a rule, patients will rest well if the nurse will not disturb them every two or three hours during the night to give nourishment and stimulants. This is a point that I wish to emphasize: avoid as much as possible disturbing a patient during the night. Rest is essential to health, and, of course, a patient needs it. Let him sleep until he awakes of his own accord. If the tongue is dry, I give for a day or two small doses of turpentine in capsules, or else I give a small dose of creosote or carbolic acid and tincture of iodine. I have the patient's mouth cleansed three or four times a day, and direct him to chew tolu an hour or two every day until the tongue becomes moist. I direct him to take as much water as his stomach can conveniently absorb.

As I pay special attention to the stomach, I do not forget the rectum and colon. These require as much attention as the stomach. I have the colon irrigated two or three times a day with warm sterile water, and if there has been a diarrhœa I use boric acid or a very weak solution of permanganate of potassium. These injections free the lower bowel and prevent any putrefaction or absorption, and thus relieve the system of what gives us that dull, characteristic expression, the foul tongue and sordes upon the teeth, the low muttering delirium that our text-books call the typhoid state. This is a phrase that I am sorry has ever found its way into our vocabulary. I hope it will soon become obsolete.

I have the patient's entire body sponged in warm water once or twice a day. If a bath tub is available, I have the patient immersed in the warm water, and the bath is kept up for from ten to twenty minutes. The body is wiped dry and the patient returned to bed. A warm bath given at night produces sleep like a sedative. I never use cold water, for it is not grateful to the patient and causes shock that is unnecessary. I find the warm water has sufficient antipyretic effects. It keeps the skin active. If water is not taken by the stomach in sufficient quantities, I give an injection of about one pint of decinormal saline solution into the colon after it has been irrigated.

I pass to Case B. This class of cases gives us much trouble, because we begin the struggle at a disadvantage, but we have an opportunity to use the same care and judgment as in Case A. Most chronic diseases are in the lungs, kidneys, heart, or alimentary canal. Of these the diseases of the alimentary canal are the most difficult. I have had consumptives pass through typhoid fever as easily as a robust patient, but those unfortunate dyspeptics are a source of worry to the physician. We must watch digestion with special care. If there is myasthenia with fermentation, we must give a very small amount of food, easily digested and slow to ferment. The white of an egg suits this class of patients better than any food. The myasthenic stomach digests it better and it usually leaves the stomach empty in two hours, and this leaves about sixteen hours' rest for a stomach that does not know what rest means, and I assure you it will be glad that its owner has had typhoid fever. Do not give milk to a patient with weak digestive power. Antiferments may be given if necessary. Bismuth, turpentine, carbolic acid, or two or three grains of chloral act very well. The stomach tube is the best preventive that we possess.

If the stomach is irritable or there is hyperchlorhydria, give sedatives just before food is taken. A cup of hot water and a large dose of bismuth will usually prove efficient. These cases improve as the food is decreased in quantity and changed in quality. I have found that irritable stomachs with hypersecretions are the result of too much food improperly masticated or cooked.

Complications must be watched for, and each met by proper remedies.

The colon is irrigated and the baths are used as detailed in Case A.

By promoting digestion and preventing indigestion, and keeping the alimentary tract from stomach to anus free from absorbable toxins, we will have no necessity for an average temperature of over 100–101° F., and a pulse 72 to 80 per minute. The sum total is: Favor digestion, prevent absorption of toxins, and promote thorough eliminatation of the toxins unavoidably absorbed.

## FACTS AND FALLACIES IN URANALYSIS.[1]

By THEODORE WILLIAM SCHAEFER, M.D.,

LATELY PROFESSOR OF CHEMISTRY, UNIVERSITY MEDICAL COLLEGE, KANSAS CITY, MO.

For some time it has been my desire to write upon a subject pertaining to uranalysis to which writers on urinary diagnosis have paid but little attention in recent years. I wish to emphasize the fact that there are certain points in analysis of the urine, especially those pertaining to the clinical significance of certain ingredients in the urine and their relationship to disease, which need further elucidation.

Although I admit that our present knowledge of this subject may be said to be in perfect accord with the advances made in the other departments of medicine, yet I am constrained to remark that certain facts, well known only to those who have made an extended and thorough study of the subject, are not generally known to the practitioner of medicine at large. Many look upon the methods of uranalysis as rather occult and shrouded, as it were, with a kind of chemical mystery. Chemistry has always been a bugbear to the average medical student and practising physician.

What I purpose to say this evening is possibly a little ultra to what is generally believed by those who have not had the time or leisure to give the subject the attention which it deserves. To begin with, I will take up the boiling test for albumin in the urine, which I will demonstrate to you as rather unscientific and misleading, although tenaciously adhered to by many practitioners of medicine. It seems to be a paradox that man cannot move out of the sphere of antiquated beliefs and customs. The boiling test, historically speaking, is one of the oldest tests for the presence of albumin in the urine. Purdy, in his otherwise very excellent work on uranalysis, mentions the name of Contugno, to whom he ascribes the honor of having first made the boiling test for albumin in the urine in 1770. I find, on searching for further historical data, that Purdy is mistaken in claiming the priority for Contugno. Richard Neumeister, in his valuable work entitled "Lehrbuch der physiologischen Chemie," which is one of the best of its kind published on physiological chemistry, gives the honor, on page 807, to Friederich Deckers, a professor of medicine in Leyden (1647–1720), who was the first who employed the boiling test with the addition of a few drops of acetic acid for the detection of albumin in the urine. He observed that the clear, albuminous urine assumed a milky-like turbidity on heating, and that by adding one or two drops of acetic acid on cooling a white coagulum was produced, whose caseous particles were thrown down, while others floated upon the surface, the urine behav-

[1] Read before the Kansas City Academy of Medicine, June 3, 1899.

ing very much like diluted chyle.[1] (Translated from the German by the writer.)

The boiling test for albumin is an unreliable as well as unscientific procedure, and should not be depended upon at all. Why physicians should cling to it so tenaciously I cannot explain except upon the psychic ground of the influence of beliefs; for a belief, right or wrong, ultimately develops into a blind faith. It is the purpose of this paper to expose the fallacy of the belief in the efficacy of the boiling test. The majority of physicians rely upon this test for albumin altogether, because it is so simple and easy to perform.

"If a sample of clear urine be heated and if a turbidity result, it may be either due to albumin or earthy phosphates. On the addition of a few drops of acetic or nitric acid the turbidity due to earthy phosphates will at once be cleared up, while the cloudiness due to the presence of albumin will not disappear; on the contrary, will be increased. A clear, faintly acid, or amphoteric urine, containing no albumin, is liable to become turbid on heating. If not enough acid be added to amphoteric urine, the precipitate of calcium phosphate is liable not to dissolve completely, and this may cause it to be mistaken for an albumin precipitate. If a little nitric acid be added so as to render the urine slightly acid, a fact which must not be overlooked, the urine will not give a precipitate on boiling, although a considerable amount of albumin may be present. The reason for this is that the addition of only a little acid occasions a combination between it and the albumin, producing an acid albumin or syntonin, which is not coagulated by heat. The same thing may happen when the urine is very highly acid from the natural causes of its acidity. If now no precipitation occurs, the acid albumin may readily be precipitated by the further addition of nitric acid. If, on the other hand, says Purdy, the nitric acid is insufficient distinctly to acidify the urine, and the phosphates are in excess, a part only of the basic phosphates may be acidified, while the albumin may combine with the remainder, forming a soluble alkali albuminate, which will not be precipitated by boiling. From what has just been stated it will appear evident that a precipitation occasioned by boiling a sample of urine cannot be positively ascribed to albumin, and that an accurate diagnosis for nephritic disease cannot be made by heating the urine alone. If a precipitation occurs on the addition of nitric acid, which is dissolved at once on boiling and then again forms on cooling, we have to do with albumose. The natural acidity of the urine is due to dihydrogen-phosphate; besides this we have in almost every sample of urine a considerable proportion of free carbonic acid which holds the earthy phosphates in solution. A previously acid urine becomes neutral or even alkaline on boiling, with the formation of a sediment which dissolves at once in acetic or nitric acid. An excess of nitric acid does not dissolve a precipitate produced by boiling a sample of albuminous urine. The boiling test should be principally used to differentiate samples of turbid urine, the turbidity being due to an excess of urates or phosphates. A turbid urine due to an excess of urates becomes clear on heating, while one due to phosphates does not. On slightly warming an albuminous urine rendered turbid by the presence of urates, the latter are dissolved and the urine becomes clear.

"Although the boiling test gives apparently good results in the hands of experts, it is on the grounds just mentioned not to be recommended to physicians as a positive and reliable test for albumin."[2]

As the precipitate due to calcium phosphate so strikingly resembles the one due to albumin in appearance, it will, as a matter of fact, occasion confusion. The writer of these lines has seen time and time again physicians simply boiling samples of urine when testing for albumin. This misleading test rejects an applicant for life insurance, and makes an otherwise healthy person unhappy and subjects him or her to unnecessary medication. This error, let the truth be said, is repeated every day by physicians engaged in private as well as hospital practice. The errors alluded to may all be avoided by not boiling the urine at all, and resorting to the nitric-acid, picric-acid, and ferrocyanide-of-potassium and acetic-acid tests, which are very simple and reliable tests for albumin in the urine. If the urine be turbid it should be first filtered before applying the tests.

Right here is the proper place to make some pertinent remarks in regard to the so-called clinical significance of the phosphates in the urine. From the transformation of tissues rich in proteid or phosphorized nerve substance in the body we might perhaps expect an equal relation between the nitrogen and phosphoric acid in the urine. Many investigations have been made upon this subject by Zuelzer, Struebing, and Edlefssen; but all the conditions which affect the elimination of phosphoric acid are not yet sufficiently known. It is difficult to draw any definite conclusions from observations thus far made. The phosphoric acid of the urine originates to a small extent from the burning of organic compounds, nuclein, protagon, and lecithin, within the organism (Hammarsten). In this connection I should not forget to mention the observations of Edlefssen, who pointed out the relation existing between the destruction of leucocytes and the excretion of phosphoric acid.

Little is positively known in regard to the elimination of phosphoric acid in disease. The statements in regard to the amount of phosphoric acid excreted in a number of diseases are contradictory and need further confirmation. As is apparent from the data given, our knowledge concerning the excretion of phosphoric acid is as yet in its infancy, and the causes producing variations in its amount are very obscure.[1]

It is also apparent that important conclusions cannot be drawn, on the whole, from a knowledge of the absolute phosphatic elimination, for the greater part originates from the phosphates of the food, and the quantity of eliminated phosphoric acid is greater when the food is rich in alkaline phosphates in proportion to the quantity of lime and magnesia phosphates. The extent of the elimination of phosphoric acid by the urine depends not only upon the total quantity of phosphoric acid in the food, but also upon the relative amounts of the alkaline salts in the food (Hammarsten).

In accordance with these considerations there appears to be no demonstrable relationship existing between the excreted and variable quantities of phosphoric acid in the urine and the pathological tissue change, although this has been repeatedly claimed, even in very recent times.[2] (Translated from the German by the writer.)

Observations made upon the phosphatic excretion during muscular exercise have not given uniform results, apparently depending upon the nature of food, as a decrease, no effect at all, and an increase have been reported by different observers. Mental exercise appears to cause a diminished excretion of alkaline phosphates and an increased elimination of the earthy phosphates. The latter also takes place during sleep

(Simon). From what has just been said it will appear at once obvious that we must place the phosphates in the doubtful list, as far as their clinical significance is concerned, and an estimation of their total amount can benefit only the urinalyst and not the patient. Will the average chemist and urinalyst tell you this? I doubt it.

We now come to a phase of the subject which is attracting the attention of the medical profession, and that is the reputed rôle of uric acid[1] in disease. Uric acid is nowadays held responsible for a large number of pathological conditions. It is claimed by many writers to be the causal factor of at least thirty-nine separate morbid conditions.[2]

The uric-acid theory is now the great pathological fetish of the medical profession. It is contended by many writers, foremost among whom is Haig, the great apostle of the uric-acid theory, that uric acid is the responsible factor, the *fons et origo mali*, of a large number of ills and aches. This is a great question, and it is the firm conviction of the writer that the day is not far distant when we shall be obliged to give up the uric-acid hypothesis altogether and be compelled to look for causes elsewhere. The amount of uric acid excreted in twenty-four hours ranges from 0.4 to 1 gm. (gr. vi. to xv.). The quantity of uric acid in the urine should never be presumed to be excessive from the mere fact of deposit of uric-acid crystals in the urine upon cooling, as in fact such may, and very often does, occur when the uric acid is both relatively and absolutely deficient. The conditions of the urine which tend to precipitation of uric acid are as follows: (1) High grade of acidity of the urine; (2) poverty in mineral salts; (3) low percentage of pigmentation; (4) long standing. Any urine upon standing will deposit uric-acid crystals in consequence of the changes culminating in ammoniacal decomposition.[3]

Now a word or more in regard to the so-called brick-dust sediment of the urine. I will say that it is usually not of much diagnostic value, although physicians frequently attach great importance to it. A uric-acid sediment is observed in cases in which an increased excretion of uric acid occurs, but it should be remembered that, as a rule, it is not permissible to infer an increased production or elimination from the presence of an abundant deposit of urates alone. Brick-dust sediments are frequently observed in the urine during winter months; but nothing would be more erroneous than to infer an increased elimination from such an observation, as the phenomenon in nine out of ten cases is explained by the fact that uric acid is far less soluble in cold than in warm water. According to Bunge,[4] it takes about fourteen litres of water at the ordinary temperature of the room to dissolve 1 gm. of uric acid; at the boiling temperature it requires two litres, and at the temperature of the body seven to eight litres. The acid urate of sodium dissolves in eleven hundred parts of cold and one hundred and twenty-four parts of boiling water. Much more difficultly soluble are the urates of ammonium and those of the alkaline earths. (Translated from the German by the writer.)

During summer months a deposit of urates is less frequently observed, although an increased amount may nevertheless be present, being held in solution owing to a higher temperature. The more concentrated the urine and the more uric acid it actually contains, the more readily will a deposit of the kind occur. Uric-acid sediments are most often encountered in very acid urines (Purdy). Horbaczewsky and others have shown in recent years that enormous amounts of uric acid are excreted under a diet rich in nucleins, thymus having been employed in the cases observed.

Now permit me to express a few words in regard to the so-called uric-acid diathesis, particularly gout and its relationship to uric acid. It has long been a matter of doubt in my mind as to whether uric acid has actually any causal connection with the varied manifestations pictured under the name of uric-acid diathesis. Recent investigations seem to show in a very conclusive manner, notwithstanding numerous statements to the contrary, that the excretion of uric acid in gouty patients moves in the same wide limits as in the healthy. In this disease the urates are neither increased nor diminished in any stage. An increase of uric acid in the blood of gouty patients has not been established with any great degree of certainty. Von Noorden has arrived at the conclusion that the gouty condition is independent of the presence of uric acid in the blood. This experimenter holds the opinion that the gouty process can be traced back to a specific local inflammation of the respective tissues. Changes occur which show partly the character of an inflammation, partly that of a necrosis. The acuteness of the process and other conditions may produce a slight or an abundant deposit, or even a deposit entirely free from uric acid. The uric acid which is once formed remains *in loco* at the necrotic areas, because it is insoluble in the fluids, notwithstanding their alkalescence. In leukæmia the presence of uric acid is greatly increased in the blood and in the tissues, and yet no gouty deposits nor symptoms characteristics of gout occur. This late view of the nature of gout seriously questions the rationale of the treatment at present advocated against the malady in question. Besides, clinical experience teaches clearly enough the absolute immunity of gouty nodules against alkaline medication.[1] (Translated from the German by the writer.)

From what has been just stated it will appear obvious that the value of a quantitative estimation of uric acid and the clinical deductions drawn therefrom will remain an open question. Much more could be said on this interesting subject; by extending it I would be obliged to write a separate paper.

In recent years much attention has been paid to the clinical significance of calcium oxalate in the urine and certain deductions drawn from its presence in that menstruum in a number of pathological conditions. Oxalic acid was first discovered in the urine by W. H. Wollaston.[2] Subsequently it was detected in the same fluid by A. F. de Fourcroy,[3] and its constant occurrence was established by C. G. Lehmann.[4]

It is my conviction that calcium oxalate should be placed in the doubtful list as far as its significance is concerned in disease. The group of symptoms described as characteristic of oxalic diathesis may be due to other causes, for it has not been positively established whether oxaluria may occur as an independent disease. Here, as elsewhere, the faking urinalyst has an opportunity to prey upon the confidence of unsuspecting physicians. In almost every sample of urine crystals of calcium oxalate can be detected. "Numerous crystals of the oxalate may be seen, when a quantitative estimation actually shows a diminution of the normal amount" (Simon). In certain pathological conditions oxalic acid is greatly increased; the cause of this, however, we cannot explain. As it passes un-

[1] Uric acid was first discovered in human urine in 1776, by C. W. Scheele.

altered from the system, it can be easily detected in the urine, when certain kinds of vegetables are partaken of as food.

The most popular method of searching for the presence of sugar in the urine has been the Fehling's-liquor test, and yet how many physicians have had their troubles with it! Why? Because some degree of experience is necessary in order to make a satisfactory test for sugar. The chief objection to Fehling's solution is its instability. Reducing substances in the urine frequently change the blue color to a slaty green. In testing with this solution errors are made almost every day by physicians, for precipitations and discolorations due to natural causes (phosphates, uric and oxaluric acids, etc.) are often attributed to sugar, when the urine is entirely free from the latter. It is needless for me to repeat that some degree of practice—the tactus eruditus—is necessary in order to determine the exact point of reduction.

We have heretofore been generally taught the great significance of tube-casts in the urine, which were regarded as indicating invariably a grave lesion of the kidney. This view, says Simon, has been abandoned, however, for the same reasons which led to the rejection of the theory that albuminuria invariably indicates Bright's disease. In examining for tube-casts it is essential to draw a distinct line of differentiation between true casts, pseudo-casts, and cylindroids. Only the true casts, consisting of a uniform, transparent, gelatinous matrix, to which other elements, such as epithelial cells, red blood corpuscles, leucocytes, and salts in a crystalline or amorphous form, may accidentally have been attached, should be regarded of great diagnostic value. Inexperienced students and physicians often mistake cotton fibres and cast-like formations, which consist entirely of amorphous urates, leucocytes, and even bacteria, for coarse granular casts.

Mucous casts are frequently mistaken for regular tube-casts, but the absence of albumin, together with the other conditions of the urine to be elaborated, will render a mistake in diagnosis in these cases highly reprehensible.[1]

Hyaline casts, too, even in urine with or without albumin, have been noticed temporarily during certain fevers, which might be mistaken by the novice for acute nephritis. Hyaline casts have been noticed at times in the urines of apparently healthy persons.

As desquamative processes are continually going on in the epithelial lining of the various cavities and channels of the body, we should naturally expect to find in every urine representatives of the different forms of epithelium occurring in the urinary organs, from the Malpighian tufts down to the meatus; their presence in large numbers in the urine, however, should be regarded as pathological. Were it possible, says Simon, in every case to determine the exact origin of the cells observed, it is clear that information of great value could be thus obtained, and that it would be a comparatively simple matter to localize the seat of lesion. Unfortunately this is not always possible, as the form of the cells is dependent to a certain degree upon the reaction of the urine, an alkaline or neutral reaction causing the cells to swell and to appear larger and rounder than is the case in acid urines. The cellular type is practically the same in the bladder, ureters, and pelvis of the kidneys.

What I have said of the histological elements, the epithelial cells along the urinary tract, applies also to the leucocytes. Leucocytes are encountered, though in very small numbers, in almost every healthy urine. I have repeatedly detected them in a number of normal urines. A marked increase, however, should always be regarded as indicating the existence of disease somewhere in the course of the urinary tract. By the leucocytes alone we are not able to locate the particular area of disease in the urinary tract. In females the presence of a large number of leucocytes may be due to an admixture of leucorrhœal discharge, containing large pavement epithelium of the vaginal type.

Before closing I would like to make a few remarks in regard to the clinical significance of Ehrlich's diazo reaction for typhoid fever. This reaction has been regarded as pathognomonic of typhoid fever. In the past I have made a number of experiments with urines of typhoid fever and other diseases, and have arrived at the very same conclusions expressed by von Jaksch, that we cannot ascribe any clinical significance to this test whatsoever. The color reaction characteristic of typhoid fever I have noticed even in perfectly healthy urines.

## DEMONSTRATION OF TWO CASES OF EXSTROPHY OF THE BLADDER, WITH SUGGESTION FOR A NEW OPERATION.[1]

By J. H. BRANTH, M.D.,
NEW YORK.

Exstrophy or extroversion of the bladder is a fissure in the lower abdominal wall, extending backward into the bladder. The posterior wall of the bladder is pushed through this fissure, protrudes, and spreads out everted on the surface. Of course, the ureters conduct the secretion from the kidneys through this fissure into the bladder wall, and one can see here the mouths of the two ureters. The two cases I present are so much alike that a demonstration of one will also answer for the other. As the parts are more prominent in the older patient, a boy of nine years, I will use this patient first for illustration. This child and also the younger patient, a boy of nine months, have been photographed.

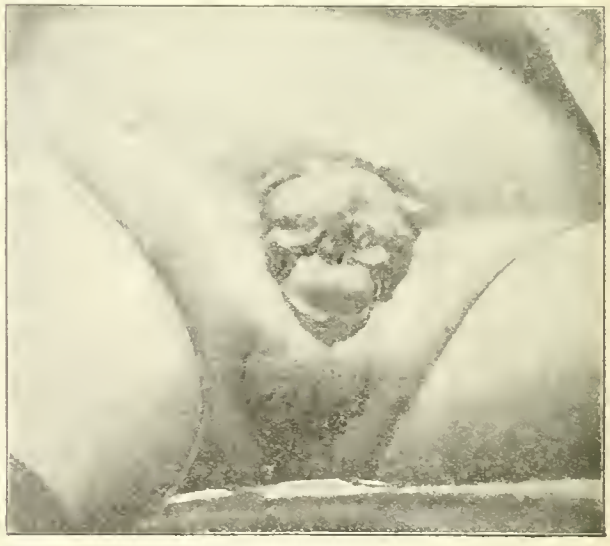

Fig. 1.

The mouths of the ureters continually weep; at times, on abdominal pressure, they spurt out the kidney secretion. The abdominal muscles are behind the bladder. The penis is epispadic, which means that the part above the roof of the urethra is missing. The penis in all the cases I have seen is located above the pubic commissure; the pubic bones I have noticed in all cases to be abnormally small.

[1] Presented at the meeting of the Medical Association of the Greater City of New York, held at the Fifth Avenue Hotel, June 12, 1899.

As the cause of this somewhat rare malformation I would advance the theory that in the first weeks of fœtal life, when the abdominal cavity is open, and the allantois and umbilical vesicle communicate with it, when the fœtal body is bent in a crescentic form, when

Fig. 2.

the bony structures are in a very soft and flexible condition, by some accident the pubic bone tissues are twisted on their horizontal axis, by which the tissue to form the penis (the latter is covered with elements to form true skin) is brought out over the pubic commissure. Now, the skin element of the penis covering will prevent union of the two sides of the linea alba; the bladder will later be pushed through and everted, and so a non-union of the linea alba up to the point of insertion of the umbilical cord will result. If we examine a skeleton of a six months' fœtus, a glance at the pelvis will show what a small displacement, such as I have mentioned above, could produce the effect as seen in these two patients. I have here also a photo-

In operating on these cases, Simon, of St. Thomas' Hospital, diverted the renal secretion into another channel, but the patient, a boy of thirteen years, died from disease of the ureters and kidneys, caused by the new association of organs. Lloyd and Athol Johnston's patient, similarly treated, died from peritonitis. In Ashhurst's "Surgery" it is stated that plastic operations of varying details have been employed by several surgeons. Professor Pancoast, of Philadelphia, has the honor of having performed in 1858 the first successful plastic operation to cover up by skin flaps the protruding, everted, and misplaced bladder. In the same year Ayres, of Brooklyn, made a successful plastic operation. F. F. Maury, of Philadelphia, had two successful cases. Wood, of King's College, London, has had eight cases. In all of these operations the plan was to cover the bladder with double skin flaps, turned on the pedicle. Natural voidance of urine is out of the question; all that is aimed at in this operation is to cover the exposed mucous membrane and shield it from irritation. I have never seen such a case after operation, but think that the true skin, inverted to make an anterior wall for the bladder, would insufficiently perform the function of mucous membrane, and would continuously suffer from excoriation, causing misery to the patient. The growth of pudendal hair on the then inner surface of those flaps must cause additional trouble; however, nature would probably leave an opening large enough to permit the introduction of a pincette to remove hairs and incrustations.

In Bigelow's operation the mucous membrane is peeled off, and skin is shifted over it to cover the tumor, of course leaving the ureters untouched, in this manner reducing the exposed portion to a small area. Now, as the fundus of the bladder and the penis rise over the pubis, climb over it, if you please, all the above operations will leave a weak spot, a notch, over the pubis, which region is liable at any time to yield like a notch in the selvage of cloth.

Some three years ago I operated on Charley C——,

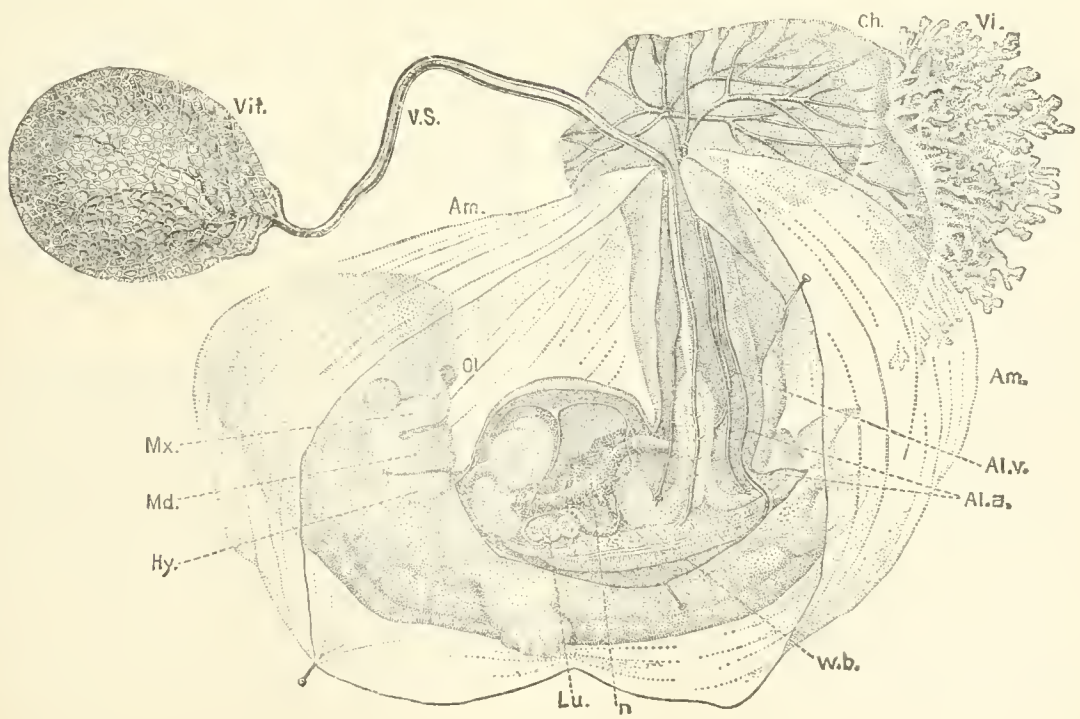

Fig. 3.

graph of the Coste fœtus, copied from the "Reference Handbook of the Medical Sciences," which shows the position of the abdominal organs on the thirty-fifth day of fœtal life.

the elder patient, assisted by Dr. W. T. Warster as etherizer and several others, on a plan partially described hereafter, except that I did not transfix the penis from its improper position, nor did I lower the

bladder into the pelvis. The ureters were catheterized by thin rubber drainage tubes, which were led out over the epispadic penis, so that no renal secretion should reach the bladder during repair. The bladder was closed by Lembert sutures and crowded into the fissure behind the muscles into the abdominal cavity. After this it was no hard task to close the fissure, stitching the raw surfaces together layer by layer, with catgut. All went well until by accident one rubber tube became clogged; it was freed, however, by suction with a syringe; then the other tube became dislodged by violent tossing caused by an attack of toothache; the renal secretion then ran over the operative field, and we had to open the wound. Partial union had occurred, but in a few days nearly everything parted again. I have gained something, however; that is, a thick wall of tissue, so that the patient can now wear a cup connected with a urinal. This thick wall of tissue will enable me to make a stronger suture and union of parts at a future operation, which will include reposition of the bladder and penis, by which procedure the bladder will be lowered behind the pubes and into the pelvis, making the whole work much more easy.

I shall make an incision just anterior to the scrotum and below the pubes, and by a hook draw out the penis through this incision. The fundus and almost the whole bladder will be lowered into the pelvis, behind the pubes, where it will be fastened by catgut stitches. Of course the bladder will before this be closed by Lembert sutures and detached from adhesions above. The root of the penis will be made raw and stitched to the edge of the wound through which it now protrudes. We shall now have the bladder in the normal position. The tendinous portions of the transversalis and oblique muscles, ensheathing the rectus muscles, can now be easily stitched together (the parts lie almost together) by continuous and recurrent suture, similar to that used in modern perineorrhaphy, to secure a firm union; drainage of the renal secretion through the groove in the epispadic penis, the defective urethra, will of course be necessary. Later on efforts to build a roof to the urethra will become another problem, which seems a possible achievement, if the plan up to this stage be successful.

Considering first all the older operations, none of which attempts a restoration to the natural position and relations of the parts and organs, and then considering my plan, I think I shall have the aid of nature to lead to success; and if the operation is successful normal function and natural position will be approached.

Let me make, in closing, a remark about the testes. They are in the groin in both cases. If they remain in their present position, they will probably not undergo the change to puberty, and hence the patients will probably always be sterile. This is a common observance in all cases of undescended testes. If I meet with success in my above-described operations, I shall then attempt to bring down the testes to their proper receptacle, where they are comparatively shielded from injury.

183 West Eighty-seventh Street.

---

**Digitalis in Granular Kidney.**—A persistently high tension, to whatever cause due, is of itself pernicious, but not so with granular kidneys, paradoxical as this may seem. The patient is best without granular kidneys, but if the kidneys be granular it is better that the tension should be high rather than low; in other words, the patient is worse with a low tension, and this explains the benefit of digitalis in such cases; it does so much good by raising the arterial tension. —Samuel West, *Pacific Medical Journal*, April.

## Progress of Medical Science.

**Post-Anæsthetic Paralysis.** — As the result of a study of the paralytic states that develop in the sequence of some surgical operations performed under general anæsthesia, Mally (*Revue de Chirurgie*, July 10, 1899) concludes that two groups of cases appear to be in no way related to the anæsthesia, namely, those presenting hysterical and reflex palsies. Central palsies due to cerebral hemorrhage are rare in which the anæsthesia appears to have induced rupture of a vessel through purely mechanical influences. Peripheral palsy is, however, a common complication. It always results from compression, and the influence of the anæsthetic is only indirect, permitting involuntary and accidental compression of nerve-trunks or plexuses. The anæsthetic may besides exercise some toxic or depressing influence upon the nervous system, but this is purely hypothetical. The preventive treatment consists in the avoidance of strain, pressure, or constriction. Peripheral palsy due to compression should be treated with localized faradization as early as possible unless degenerative atrophy be present. Impaired mobility at the shoulder may be averted by early passive motion. Profound reflex palsy should not be treated with local electrization, but with sedative applications of the static current to the nape of the neck, and, in accordance with indications, with revulsion of the vertebral column by means of the actual cautery.

**The Nature of the Gouty Nodule.**—As the result of an experimental investigation, Freudweiler (*Deutsches Archiv für klinische Medicin*, Bd. 63, Hft. 3 u. 4) attributes the formation of the gouty nodule to the inflammatory reaction of the tissues to the irritation excited by the deposition of sodium biurate and manifested by inflammatory infiltration, with swelling of the affected structures. It is considered improbable that the crystalline deposit is preceded by tissue-necrosis, inasmuch as on the one hand sodium biurate is incapable of causing complete necrosis, while on the other hand the crystalline needles have been found in anatomically intact tissues. The disappearance of gouty nodules is attributed to the activity of phagocytic cells, as there is no evidence to show that the crystalline deposit is removed by the simple physical or chemical action of the fluids of the body. The restoration of the deficiency thus resulting is effected through centripetal hyperplasia of the connective tissue of the adjacent structures, which at the same time surrounds the area with a more or less dense fibrous capsule, so that eventually it is cut off from all relation with its surroundings.

**The Treatment of Diphtheria with the Antitoxin.** —Wenner (*Archiv für Kinderheilkunde*, B. 27, H. 6, No. 2) reports the result of an analysis of the cases of diphtheria treated in the diphtheria department of the Children's Hospital at Zurich from October 25, 1894, to December 31, 1898. There were received five hundred and twelve patients, of whom fifty-two died (10.1 per cent.). Diphtheria bacilli, however, were found only in four hundred and thirty-two, of whom forty-four died (10.18 per cent.). Of these four hundred and thirty-two cases only eight were, for various reasons, not treated with antitoxic serum. Comparative observations show that the mortality for all cases has been reduced from forty-three per cent. between 1874 and 1894 to ten per cent. between 1894 and 1898; in the cases in which intubation or tracheotomy was required the mortality has been reduced from 63.7 per cent. to 19.4 per cent., and in those requiring no operative intervention from 15 per cent. to 5.8 per cent. It was found that as a result of the use of the serum

the temperature declined rapidly to the normal in the majority of cases, whether the injection was made early or late in the progress of the disease. Exfoliation of the deposit is more rapid and in almost all cases uniform. The influence upon the stenotic manifestations is most distinct. After the injection extension of the disease to the pharynx and the larynx and exacerbation of the stenosis are not observed. Marked albuminuria, nephritis, and paralyses are not to be considered as sequelæ of the injections, but as a result of the activity of the diphtheria toxin. The serum causes various exanthems, often even fever, but these are never attended with further serious consequences. Individual serums present differences in this respect. In no case has death or injury to health resulted from the injections. For the foregoing reasons the employment of the serum is warmly indorsed for both hospital and private practice.

**The Early Diagnosis of Pulmonary Tuberculosis.**—At a recent meeting of the Société Médicale des Hôpitaux, Fernet (*Lancet*, August 12, 1899) described a special combination of physical signs in the incipient stage of pulmonary tuberculosis, and to which he attributes diagnostic significance. This consists in the simultaneous existence of physical signs on the same side at the apex of the lung, in the interscapular region at the level of the bronchial glands, and at the base of the lung. At the apex there occurs modification of the percussion note, with change in the respiratory murmur and adventitious sounds on auscultation. Tracheo-bronchial adenopathy gives rise to dulness on percussion and resistance to the finger in the interscapular region on the side of the diseased lung at the level of the upper dorsal vertebræ, while on auscultation hollow, almost cavernous breath-sounds are heard, the expiratory sound being the louder and the longer. At the same time there is often axillary adenopathy on the diseased side. Finally, impairment of percussion resonance and subcrepitant râles are found at the base of the affected lung posteriorly. Sometimes, however, there is in some places slight tympany, with enfeeblement of respiratory murmur, harsh respiration, or fine crepitation.

**Successful Removal of One Testicle for Prostatic Enlargement in a Man Aged Eighty-seven Years.**—Drs. Webber and Duffet report in *The Lancet*, August 1, 1899, the case of an unmarried man, eighty-seven years old, who complained of difficulty of micturition, which he attributed to a chill acquired two days previously. A mixture containing potassium bicarbonate and tincture of hyoscyamus was prescribed, together with an aperient dose of magnesium sulphate. Very little urine, however, continued to be passed, and the bladder was found to be distended, its fundus reaching almost to the umbilicus. The prostate was uniformly enlarged. With the help of the finger in the rectum a No. 8 rubber catheter was introduced into the bladder and about two pints of normal urine were withdrawn. The catheter was thus employed daily, with increasing difficulty, for five days, when no instrument of any sort could be introduced. The distended bladder was accordingly tapped above the pubes with a trocar and cannula, which was tied in place until the following day, when it was replaced by a No. 7 catheter closed by a plug. This was pulled out by the patient, and leakage of urine resulted. A large bed-sore formed, and the urine became ammoniacal. After a while, the symptoms increasing in gravity, it was decided to remove one testicle under local anæsthesia, and if necessary and possible to remove the other later. Accordingly, after injection deeply of seven minims of a four-per-cent. solution of cocaine and application of a spray of ethyl chloride, the left testicle was removed. On the following day a soft catheter was without difficulty introduced into the bladder, but for several days subsequently this was impossible. Later, however, introduction of the catheter again became possible, and after the lapse of a little more time urine could be voided spontaneously by the urethra, while at the same time the prostate was found to be reduced in size. All of the wounds ultimately healed, and the patient recovered perfectly, reaching his eighty-eighth birthday in good health.

**Chronic Idiopathic Dilatation of the Stomach** may be looked upon as a symptomatic manifestation, of diverse and often obscure origin, occurring at any age and attacking the two sexes alike. To increase in the dimensions and change in the form of the stomach is added diminished muscular power, with lessened vermicular activity, stasis of the gastric contents, and abnormal decomposition and fermentation. Neurasthenia is often an associated condition, and sometimes floating kidney. In the treatment of this condition Glynn recommends exercise, especially out of doors, encouraging such movements of flexion and extension of the trunk as tend to strengthen the abdominal muscles. Douches and baths are useful adjuncts. A suitable support should be worn, and electricity may be employed. In some cases the rest treatment is to be preferred. Lavage may be practised with advantage. The diet should be light and nutritious. Liquids in excess are to be avoided, as well as alcohol, sweets, oils, and fats. Benefit often follows a sea voyage or a sojourn at a spa. Alkalies and bitters may be administered before meals, to improve digestion. Large doses of hydrochloric acid well diluted are useful one or two hours after meals. When there is evidence of much decomposition and fermentation a large dose of salol and of bismuth salicylate may be given at night. Thymol often relieves flatulence speedily, and antipyrin the discomfort and slight pain. In the failure of all other measures surgical intervention may be demanded. —*Liverpool Medico-Chirurgical Journal*, July, 1899.

**Fatal Poisoning with Crystals of Potassium Permanganate.**—Dr. Box reported in *The Lancet* of August 1, 1899, the case of a married woman, forty-seven years old, of intemperate habits, who, after drinking heavily, took a "handful" of crystals of potassium permanganate, and, throwing them into a teacupful of beer, drank the mixture. In a short while she vomited, and later became pale and unable to speak, although retaining consciousness. The lips, chin, fingers, and the front of the right forearm were stained dark brown. The tongue was much swollen and almost black in color. The breath smelled strongly of stale beer. The skin was dry; the pulse was moderately rapid and of fair tension. When, after a few moments, the woman struggled into a sitting posture, her breathing became accompanied by slight stridor. Preparations were immediately made for tracheotomy, but before anything could be done she fell back pulseless, and the respiration ceased. The heart could be heard beating faintly and slowly after the pulse was no longer perceptible at the wrist. Artificial respiration induced one or two respiratory movements, but beyond this was of no avail. The heart-sounds ceased altogether a few minutes later. Death occurred thirty-five minutes after the ingestion of the poison. Upon post-mortem examination, in addition to the deep brown staining of the chin, the lips, and the interior of the mouth, the front part of the tongue was found to be swollen and almost black, while the back part was of a deep mahogany color. The upper part of the epiglottis was blackened, as was also its laryngeal aspect. The glottis was œdematous in a moderate degree. A small speck of blackening was seen on the anterior wall of the trachea

below the glottis, but, with this exception, the mucous membrane of the trachea was natural in appearance. The stomach was moderately distended and presented no sign of inflammation externally. It contained about two pints of fluid with which was mingled a black, insoluble powder and some parchment-like masses, the latter probably portions of food. The gastric mucosa was coated with a black, granular powder, which was closely adherent and could not be washed off. On scraping away the incrustation the mucous membrane was found to be intensely hyperæmic and presenting a bright pink blush. The destructive action of the salt was evidently very superficial. A little of the black deposit had escaped into the duodenum, the mucous membrane of which also was hyperemic, but without incrustation. The liver was enlarged and appeared fatty. The portion of the spleen near the stomach was soft and pultaceous; the rest of the organ was normal. The kidneys were tough and somewhat diminished in size; their capsules were adherent and when stripped exposed granular surfaces; the cortices were wasted. The left ventricle of the heart was hypertrophied and exceedingly firmly contracted. The cusps of all the valves were thickened. The lungs were deeply congested and œdematous. There was somewhat extensive atrophy of the left superior frontal convolution of the brain, and a considerable subarachnoid collection of fluid lay over it.

**Leukæmia and Leucocytosis.**—At the German Congress for Internal Medicine recently held at Carlsbad, Löwit (*Wiener medizinische Wochenschrift*, August 1, 1899) pointed out that, while leucocytosis and leukæmia are both characterized by increase in the number of normal leucocytes, they represent two distinct processes that should be strictly separated because of their differences in nature. Leucocytosis is only a symptom of varying etiology. It may appear gradually and disappear abruptly, and vice versa. Leukæmia is always attended with leucocytosis, which is, however, not simple, the increase in leucocytes being always due to a specific cause. Reliable conclusions as to the source of the abnormal cells cannot be based upon the form and constitution of the leucocytes. As the result of his studies of leukæmia, Löwit expresses the opinion that in cases of myelæmia the peripheral blood contains a leucocytic hæmamœba, which multiplies by sporulation; permanent spores can be demonstrated in the hæmatogenic organs after death. It has not yet been determined whether multiplication takes place through chromatozoids in the blood. In cases of lymphæmia the peripheral blood rarely contains hæmamœbæ; but after death a different hæmamœba is found in the hæmatogenic organs than in cases of myelæmia. In some cases of leukæmia both forms of organism are found (mixed infection). In pseudo-leukæmic anæmia of infants and in pseudo-leukæmia of the adult hæmamœbæ are sometimes found. Leukæmic infection can be transmitted to susceptible animals, the resulting disease resembling leukæmia, pursuing the course of a chronic infection and causing death rarely within a few days, but more commonly after the lapse of several months. As a rule the blood is at first the seat of a marked, but later of a variable, increase in the number of leucocytes, with change in their constitution. The presence of hæmamœbæ can be constantly demonstrated in fresh, unstained blood; they may be less numerous in the blood-forming organs, the leucocytic parasitism appearing to manifest itself especially in the peripheral blood, although the hæmatogenic organs are also involved and may be hypertrophied. The leukæmic infection can be transmitted from animal to animal by inoculation. Artificial culture of the hæmamœbæ appears to be possible, but this is not yet established with certainty.

**Bronchiolectasis, Ulcerative Broncho-Pneumonia, Ulcerative Bronchiolitis, or Honeycomb Lung,** is described by Buchanan in the *Liverpool Medico-Chirurgical Journal* (July, 1899) as a more or less acute pathological condition affecting the finest bronchial divisions and occurring, especially in poorly nourished children, in the sequence of bronchitis, either primary or secondary to some acute disease, notably measles, whooping-cough, and diphtheria. The lesion is essentially the result of an acute catarrhal bronchitis and peribronchitis, with multiple and widely diffused secondary collapse. It is characterized by dilatation of the bronchioles throughout extensive areas of the lung or the whole of both lungs. The lung presents, on section, a worm-eaten, honeycombed appearance, from the presence of innumerable small cavities, and on its surface small vesicles filled with air. The changes may be associated with miliary tuberculosis, but in most cases thus far recorded this has not been so. In chronic cases there is, besides, irregular formation of fibrous tissue in all stages of organization, and the lung may be smaller than usual. Cough is always present and tends, as the disease progresses, to become paroxysmal. The breath, as a rule, has no fetid odor, and there may be an absence of expectoration, as young children usually swallow their sputum. Vomiting may accompany the cough, with the ejection of much pus from the lungs. The condition may not during the whole period be accompanied by fever, but close observation will reveal a rise of temperature at some time or other, reaching to from 103° to 105° F. The fever may not last long, and hence may escape observation. It is usually the expression of an intercurrent attack of acute pneumonia, which may result in another focus of the disease or the extension of one previously existing. When cyanosis is marked the temperature may fall below the normal. Clubbing of the fingers develops as the cases become more chronic. There is no proportionate relation between the extent of the lesion and the general condition. The physical signs are variable. The percussion note may be normal, or high in pitch and deficient in resonance. When the lesion is localized, and especially at the base, the note may be dull. The breath-sounds may be tubular and accompanied by sharp clicking or ringing râles; as the dilatations increase in size the râles may become gurgling or even cavernous in character. In the acuter cases tubular breathing may be absent and the râles crepitant, but diffused over large areas. Other adventitious sounds may be present, from coexisting bronchitis or pneumonia, such as rhonchi, finer crepitation, and râles. None of the physical signs mentioned is diagnostic, but they change constantly from day to day in intensity, quality, and amount. The prognosis depends to some extent upon the antecedent illness and the general nutrition of the patient. Death may supervene rapidly, or complete recovery may take place, or, finally, the condition may become chronic. The most favorable cases are those in which the lesions have been limited in extent from the first, or from having been diffuse have partially cleared up and left only a localized patch of affected lung. The treatment resolves itself into that of acute capillary bronchitis generally and especially the prevention of stagnation of secretion in the tubes. In the presence of signs of deficient aeration of the blood, inhalations of oxygen may render useful service. The general nutrition of the patient must be well sustained. In the more chronic cases cod-liver oil and tonics are requisite, with an abundance of good food. Children over six years of age may use a creosote vapor bath. Other antiseptic inhalations may be administered by means of an atomizer. When possible, change of air in a dry and sheltered locality should be recommended.

# MEDICAL RECORD:

*A Weekly Journal of Medicine and Surgery.*

New York, September 16, 1899.

## THE CLINICAL COURSE OF GASTRIC ULCER.

IT is probable that gastric ulceration depends in most cases upon some alteration in the relation between the reaction of the gastric juice and that of the circulating blood, and this may be materially contributed to by the state of the circulation and the nervous control. Most of the statistical studies on the subject have been based upon pathological evidence, and it is obvious that the conclusions thus reached must differ widely from those arrived at from clinical investigation. In the hope of shedding light on the possibility and advisability of surgical intervention in a larger proportion of cases of gastric ulcer than have hitherto been subjected to operation, Greenough and Joslin (*American Journal of the Medical Sciences*, August, 1899) undertook a study of this disease as it presented itself at the Massachusetts General Hospital between the years 1888 and 1898. During this period there were received into the medical department of the hospital thirteen thousand and ninety-seven cases of all kinds, among which there were one hundred and eighty-seven instances of gastric ulcer, a proportion of 1.4 per cent. This figure corresponds closely with that mentioned by Welch in Pepper's "System of Medicine" for Europe, but is double that of Lebert for Zurich and Breslau. A study of the comparative frequency of gastric ulcer in Baltimore, Chicago, Denver, and Boston yielded the following figures respectively: 0.43, 0.32, 0.15, 0.12 per cent., which partially confirm the statement that the disease is more common in northern than in southern countries.

Of the cases at the Massachusetts Hospital, one hundred and fifty-seven occurred in females and thirty in males, a proportion of 5.23 to 1, which is somewhat higher than that usually given. The average age of the male patients was 36.75 years, of the female 27.1 years. Three-quarters of all of the cases occurred between twenty and forty years of age. No relation could be clearly made out between trauma and the development of gastric ulcer, and occupation appeared to play an insignificant rôle in the etiology.

The symptoms present exhibited the following order of frequency: Vomiting in 95.7 per cent. of cases, pain in 92.5 per cent., hæmatemesis in 78.6 per cent., pallor in 70.1 per cent., tenderness in 69.57 per cent., constipation in 65.8 per cent. The vomiting took place at no constant time. In eighty-three per cent. of cases the pain was referred to the epigastrium, and in fifty-three per cent. it was confined to this locality. Pain in the back also was present in a considerable number of cases. In a large proportion (fifty-nine per cent.) of the cases the pain followed the ingestion of food. In a small proportion (7.4 per cent.) there was no complaint of pain at all. In half of these cases the onset was attended with severe hemorrhage, and three of this number terminated fatally. Of the remainder several also were attended with marked hemorrhage. Hæmatemesis occurred in eighty-one per cent. of the cases, and in forty-five per cent. it was severe. It ushered in the symptoms in nineteen cases, in three of which, as well as in four other cases, it led to a fatal termination. Of these fatal cases, five (seventeen per cent.) occurred in males and two (1.27 per cent.) in females. These patients also exceeded the average age for their respective sexes. Repeated hemorrhage seemed more prone to cause death than a single copious extravasation. Operation for hemorrhage was performed under unfavorable conditions in two cases, and with fatal results. Pallor was observed in eighty per cent. of cases. In most of the cases in which the blood was studied the number of red blood corpuscles was diminished, and in even greater degree the percentage of hæmoglobin. Tenderness was present in only seventy per cent. of the cases; and constipation was observed in eighty-one per cent.

Perforation occurred in six cases (3.2 per cent.), in all of which symptoms of ulcer had previously been present. As a rule the perforation set in suddenly, and in all cases it terminated fatally, although in one case the patient lived for seventy days and died of parenchymatous nephritis. In four of the cases the perforating ulcer was situated on the lesser curvature; in two of these the perforation took place anteriorly and in one posteriorly. In one case the ulcer was on the anterior wall, and in one the situation of the ulcer could not be learned. General peritonitis resulted in two cases, the ulcer being situated on the lesser curvature, in one anteriorly and in the other posteriorly. In two cases a local abscess formed, the ulcer being situated on the anterior wall in one and on the lesser curvature and perforating anteriorly in the other. In one case perigastritis prevented any untoward results, and in the sixth no autopsy was held. Only one patient suffered from perforation while on a starvation diet, and this one alone survived, dying later of nephritis, with only a fibrinous perigastritis to mark the site of the ulcer. Operation was performed in one case six hours after perforation, but as the patient had been taking large quantities of liquids the fatal result was not unexpected.

Of the whole number of cases, sixty-four per cent. were considered cured when discharged, eighteen per cent. relieved, and eight per cent. had died. Of ninety-nine of the cases investigated after an interval averaging five years, there had been recurrence in forty-one, death in fifteen, cure in forty-three; and in the fifteen fatal cases, the cause of death was gastric in eight, non-gastric in three, and doubtful in four.

The mortality was much higher among males than among females.

The results of treatment, as determined at the time of discharge from the hospital, turned out much the same whether the patients received no food by the mouth for the first few days, or only a small quantity of milk and lime-water was given for the same period. Under the first-named condition the patients remained longer in the hospital than under the second-named; and a larger proportion of the latter remained well after leaving the hospital, but these were chiefly the severe cases.

This study demonstrates, among other things, that the prognosis of gastric ulceration is less favorable than is generally stated; that hemorrhage is more fatal and the mortality generally is higher among males than among females; and that there is greater need for surgical conference to the end that operative measures may be instituted opportunely when necessary.

## PUBLIC FUNDS FOR PRIVATE CHARITY.

It is quite evident, as the result of Comptroller Coler's opposition to the needless expenditure of public moneys for private charities, that the general question of providing for such institutions from the tax levy will be viewed in future in an entirely new aspect.

To a certain extent the existence of private charities has become a recognized necessity in view of the fact that the city is avowedly unable to care for all of the sick and needy that require help.

The proper way would be for the municipality to have entire control of the expenditure of all public funds and guarantee their pro rata allotment. This has seemingly been so impossible heretofore that the unequal distributions to certain favored charities have grown into a monstrous abuse, the aggregate amount appropriated in lump sums to these private hospitals and asylums amounting during the past year to a million dollars in excess of that used by the charity commissioners.

The rule has been, notwithstanding the amount of money voted for special objects, to spend the same in some way or other during the year, and, without giving any strict business account for so doing, to ask for more when the time arrived for the next appeal. The fact that all the money was used was to be taken as the proof that it was actually needed. Naturally the demands increased instead of diminishing, and many of these institutions were not only creating paupers of their inmates, but were in turn becoming pauperized by a careless and easy dependence on public bounty.

In some instances the funds were used to pay mortgages, to add to buildings, and to balance the extravagant salaries of self-appointed officials. This was safe enough to do so long as no particular accounting for money expended was demanded. It is a well-known principle in economics that when money is easily obtained there is a corresponding tendency to unnecessary and lavish expenditure. Particularly is this the case when the responsibility of the act is distributed in the ill-defined accountability of a shiftless board of management, which is so often manifested in the stretching of official conscience to shape purely business details in conformity with the main desire to increase the value of the plant. It is plain to see from such a standpoint that the purposes of real charity are thus openly and shamefully diverted. Consequently, the determination of the comptroller to learn how the money is actually used in each case is a very proper one. The more thorough his methods are to such an end the better it will be for those bona-fide charities which do good work. If some of the alleged charities are thus driven out of the business of misappropriating funds, the better it will be for such as are fittest to survive. If these institutions cannot demonstrate their right to exist by the good work they do, they are evidently unnecessary.

In the matter of medical charity at least the medical profession has long been convinced that the subscribing public has gone to the extreme of misdirected generosity.

There is a great need for a general sifting of claims for money on the purely business basis of pro rata equivalents of service rendered. The comptroller has perfect right to insist on the most thorough investigations to such an end, and to compel a rigid accounting for all money received and disbursed. If he consistently adheres to his purpose, some very interesting developments may be brought to light concerning many of the questionable methods of obtaining public moneys which are constantly practised by not a few of the managing boards of our so-called medical charities.

## SMALLPOX AND VACCINATION.

Although the medical profession all over the world, with but few exceptions, believe in the efficacy of vaccination both as a preventive of smallpox and as a means of mitigating its severity, yet the fact is notorious that there is a large, and it would appear an increasing number of persons, especially in Great Britain, who profess to have no faith in the prophylactic properties of the measure. Within the past year the ground, as regards the merits or demerits of vaccination, has been so thoroughly gone over that is it difficult to imagine anything further remains to be said. However, the antivaccinationists are of a different opinion, and proceeding probably on the principle that "continual dripping will wear away a stone," are as active as ever in prosecuting their campaign. This being the case, it behooves the upholders of the rite to display an equal amount of energy in proving by incontrovertible facts the wonderful benefits conferred on the human race by it. The *Edinburgh Quarterly Review*, published in June of this year, contains one of the most convincing articles on the subject yet written; indeed as an argument in favor of vaccination its reasoning appears conclusive. The article in question commences by giving a lengthy history of vaccination and of the good accruing therefrom, a portion of which we will here quote: "In Sweden the population and the

smallpox mortality have both been known year by year since 1774. Before vaccination the mortality from smallpox averaged 2,045 per million. With permissive vaccination from 1802 to 1816 it was reduced to 480; during seventy-seven years of compulsory vaccination the mortality averaged 155 per million, and for ten years ending 1894 it has been put down at two per million. If Sir John Simon's estimate as to the smallpox mortality in Great Britain before vaccination, being 3,000 to 5,000 per million, be accepted as fairly accurate, and if we compare it with the mortality for the ten years ending 1894, we find that for ninety-nine people who died of smallpox in the eighteenth century only one person dies now. . . . The two conditions, a crowded and a mobile urban population, are those which chiefly favor the spread of smallpox. These conditions are present in the large towns of the United Kingdom, they are much more frequent now than they were fifty years ago, and yet the mortality from the disease has everywhere greatly diminished. . . . In Prussia vaccination has been enjoined, and revaccination has been compulsory in the army since 1874. The general mortality has been reduced to seven per million, and the army has had no smallpox mortality for years."

In other countries in which vaccination is in force the decrease of smallpox is equally well marked; in truth, the evidence in support of vaccination is everywhere overwhelmingly strong. How then does it occur that there is so great a resistance to its performance? The first in the category of its opponents are the cranks and faddists, that class of persons who, either for the sake of personal notoriety or because they possess the spirit of contrariety, are willing to overturn anything and everything. Next in order come their followers, the ignorant, those people who are ever easily led astray by a new doctrine, and who, never having experienced the fearful ravages brought about by a severe epidemic of smallpox, simply do not believe in its virulence. It should, nevertheless, in fairness be said that some of the prejudice against vaccination must be attributed to faulty administration in times past. Now that this cause of complaint has been removed, the statement may be made without fear of contradiction that nothing but good can come of vaccination. The antivaccinationists always make a strong point of sanitation, and declare that it is to efficient sanitation and not to vaccination that the doing away of smallpox is due. This contention, however, will not bear a close analysis. Those who have made a careful study of the matter say that there is no reason to suppose that smallpox is ever developed out of defective sanitary conditions. The disease is as contagious in the rich man's dwelling as in the squalid home of the poor. A striking proof of the value of vaccination and of the unimportant part played by bad sanitation in the development of smallpox has recently been afforded in Manila. Assistant Surgeon Ritchie, Thirteenth Minnesota volunteers, writing from that town says: "April and May are the smallpox months in Manila. Two hundred and fifty deaths a month was not considered an excessive number, and this under ordinary conditions and not considered an epidemic. Since our occupation no such number has occurred, and owing to the untiring efforts of Major Bourne, the mortality is almost *nil*. He told me a short time ago that there were but ten cases all told, and most of them were varioloid, so that smallpox within our lines is under control. . . . Over fifty thousand persons have been vaccinated, most of them several times, and the good work goes on." In regard to the sanitary condition of Manila, Surgeon Ritchie has this to say: "Consider its location, built upon swamp land, where every tide affects the rivers and streams for miles into the interior, so that only surface drainage can be had." Before leaving the subject of smallpox, and in view of its prevalence in parts of this country, we would again call attention to the importance of a correct diagnosis. Mistakes in diagnosis are sometimes made through the lack of a sufficient acquaintance with its lesions, and at other times owing to the type of the disease being modified by vaccination. Extreme care should be taken to ascertain with certainty whether the disease is smallpox. If it is, and is not recognized as such, the consequences to the neighboring community will probably be disastrous, for it must be remembered that so far as spreading infection is concerned the mild type of the disease is almost as dangerous as the severe, and furthermore, if the cases are not isolated, will in the course of a comparative short period develop into virulent confluent smallpox.

## FAITH CURING IN ILLINOIS.

Recently in Illinois there has been a very novel judicial decision bearing upon the legality of curing by faith. In a case of death from typhoid fever, due to neglect of proper medical treatment and the substitution of spiritual methods, the learned attorney-general held that the laws of Illinois do not prohibit the treatment of disease by the mental and spiritual machinations employed by Christian Scientists or others when no medicines are used, and further, that when a patient dies under such treatment it is not an offence under the criminal code of the State. The ingenuity with which the law is construed to that end is one of the curiosities in jurisprudence. The following is the text of the remarkable rendering:

"I am of the opinion that the criminal code has not been violated. Section 42 of an act to amend an act entitled 'An act to prevent and punish wrongs to children,' is the only provision of the criminal code that can by any possibility be held applicable to such a case. It reads: 'It shall be unlawful for any person having the care and custody of any such child wilfully to cause or permit the life of such child to be endangered or the health of such child to be injured, or to wilfully cause or permit such child to be placed in such a situation that its life or health may be endangered.'

"I am of the opinion that the word 'wilfully' as used excludes it from application to the case in hand. As there used it means 'intentionally' or 'designedly' and does not cover cases of mistaken judgment, where

the parents or persons in charge of the child honestly believe in the efficacy of the treatment adopted.

"I am also of the opinion that under the act of 1899 concerning medicine and surgery, persons may minister to or treat the sick or suffering by mental or spiritual means, without the use of any drug or material remedy, without a license from the State board of health. Christian Scientists claim to heal or cure the sick, or those who think themselves sick, by such means, and that is exactly what was done, or attempted to be done, in this case."

It will be interesting to discover what the Illinois State Society can do to offset this legal sanction of a monstrous fraud.

## News of the Week.

**Yellow Fever** has appeared at several points in the South, in New Orleans, Mississippi City, Jackson, Miss., Port Tampa, and Key West. The number of cases at Key West is quite large and increasing daily, there having been about two hundred cases to date. The disease is in mild form and very little alarm exists. A strict quarantine is, however, maintained against the infected places. Four passengers, brought to this port on a steamer from Key West, were found to be suffering from the disease, and one has died at quarantine. A dispatch from Merida, Yucatan, announces that the yellow fever has entirely disappeared from that town. Many of the Mexican coast towns are, however, still suffering severely from visitations of the disease.

**Public Funds for Private Charities.**—The comptroller of this city submitted last week to the board of estimate and apportionment his report on the private charities, for which appropriations have been made by the city, and recommended a radical reform of the present system. He said that the city is excessively liberal in its gifts to private institutions, and in support of this assertion he submitted the following table, showing the amounts of the subsidies to private charities in various cities:

| | |
|---|---|
| Chicago | $2,796.00 |
| Philadelphia | 151,020.00 |
| St. Louis | 22,579.30 |
| Boston | Nothing |
| Baltimore | 227,350.00 |
| Cincinnati | Nothing |
| Cleveland | Nothing |
| New Orleans | 30,110.00 |
| Pittsburg | Nothing |
| Washington | 194,500.00 |
| Detroit | 8,081.00 |
| Milwaukee | Nothing |
| Newark | 7,500.00 |
| Jersey City | Nothing |
| Minneapolis | 2,000.00 |
| New York City | 3,131,580.51 |

He urged that these appropriations be reduced very materially and in some cases cut off entirely, for he was convinced that ultimately the cause of charity would benefit rather than suffer from this course, for a serious objection to the whole subsidy system, he said, is that it tends to dry up the sources of private benevolence. The following is the part of the report which deals with hospitals and dispensaries: "The medical charity system should be changed so that the work of the several dispensaries of the city be limited to certain districts, with the view of preventing an unnecessary duplication of work, and that the cases treated by dispensaries should be certified to the State board of charities, which board (by means of inspectors of its own appointment, but paid for by the dispensaries) would inspect such cases and certify such of them as are proper charges against the city to the comptroller's office for payment. In the event of this plan being deemed impracticable—and thus far I have received no assurance from the State board of charities that it will be carried into effect—I suggest that the amounts allowed to dispensaries be limited to fifty per cent. of the amount received from private benevolence during the fiscal year last preceding the year in which the budget is made, the amount allowed in any one year, however, not to exceed by twenty-five per cent. the amount allowed in the preceding year, and in no case to exceed fifty per cent. of the amount actually disbursed for dispensary purposes. Fourteen hospitals in the borough of Brooklyn have dispensary attachments for which public appropriations have heretofore been made, but the finances of these dispensaries not being kept separate, it is impossible to apply the foregoing rule. In these cases I would recommend, as a temporary measure for the ensuing year only, that one-half the amounts allowed by section 230 of the charter be granted for the year 1900."

**The Plague** at Oporto continues, there being one or two deaths daily attributed to that disease. The medical professors in the university have telegraphed to King Charles, asking him to come to Oporto in person and "see the uselessness of the vigorous quarantine." They belittle the seriousness of the plague outbreak. Alexandria has been declared free from the disease, the last of the plague patients having been discharged from the hospital on September 7th. The total number of cases was eighty-nine, out of which there were forty-three deaths, or almost exactly forty-nine per cent.

**American Veterinary Medical Association.**—At the thirty-sixth annual meeting of this association, held in the Academy of Medicine, New York, on September 5, 6, and 7, 1899, the following officers were elected for 1899–1900: *President*, Prof. Leonard Pearson, dean of the veterinary department of the University of Pennsylvania, Philadelphia, Pa.; *Vice-Presidents*, Drs. J. F. Winchester, Lawrence, Mass., S. Brenton, Detroit, Mich., and H. L. Ramacciotti, Omaha, Neb.; *Secretary*, Dr. S. Stewart (re-elected), 7½ South James Street, Kansas City, Kan.; *Treasurer*, Dr. William Herbert Lowe (re-elected), 188–190 Ellison Street, Paterson, N. J.

**Examination for the Position of Assistant Physician in the Government Hospital for the Insane.**—The United States civil-service commission announces that on October 4, 1899, examination will be held at any city in the United States where the commission has a board of examiners, for the position of assistant

physician, junior grade. The examination will consist of the following subjects, which will be weighted as noted by the figures: Letter-writing, 5; anatomy and physiology, 15; chemistry, materia medica, and therapeutics, 15; general and special pathology, 25; surgery, 20; bacteriology and hygiene, 10; obstetrics and gynæcology, 10. The minimum age limitation for entrance to this examination is twenty years; the maximum none. The examination is open to both men and women, but a separate eligible register will be kept for each sex. From the eligibles resulting from this examination certification will be made to fill two positions in the government hospital for the insane, one from the male register at $900 per annum and one from the female register at $600 per annum. This examination is open to all citizens of the United States who comply with the requirements. Persons desiring to compete should at once apply to the United States Civil-Service Commission, Washington, D. C., for application forms 304 and 375, which should be properly executed and promptly filed with the commission.

**An Electric Ambulance** is being built for St. Vincent's Hospital in this city. It is believed that it will be much superior to any of the ambulances now in use, the pneumatic tires reducing the jolting to a minimum.

**The Woman's Sanitary League of Pennsylvania** has been organized at Philadelphia, with the objects of advancing sanitary science, promoting public health and good government, and forming country and local auxiliaries to extend the beneficent work.

**A New Hospital in Jersey City.**—The directors at the German Hospital and Dispensary Fund Association, Jersey City, have decided to erect a hospital in the district lying between Communipaw Avenue and the Bayonne line. At present there is no hospital in this section.

**The Wyoming State Medical Society.**—The third annual meeting of this society will be held at Laramie on Tuesday and Wednesday, October 10th and 11th, under the presidency of Dr. R. Harvey Reed, of Rock Springs. The secretary of the society is Dr. E. Stuver, of Rawlins.

**An Ambulance Surgeon's Diagnosis.**—A young man in Brooklyn a few days ago became engaged in an altercation with a fellow passenger in a street car and was struck by him with a cane. The man acted strangely and the police called for an ambulance. The surgeon who came with it diagnosed the case as one of plain drunk, and the man was accordingly arrested and fined $5 in the police court. The following day he died, and autopsy showed the existence of a fracture of the skull.

**Lectureship on Evolution.**—By the will of Richard B. Westbrook, of Philadelphia, $10,000 is devised on the death of his widow to the Wagner Free Institute of Science as an endowment fund for the maintenance of a special lectureship to "secure the full and fearless discussion by the most learned and distinguished men and women in our own and other countries of mooted or disputed questions in science, and especially the theories of evolution." In the selection of lecturers, preference is to be given to those who work for the love of truth rather than pecuniary reward, although it is intended that those employed shall receive a fair and even liberal compensation. No lecturer shall be excluded because of his belief or want of belief, if otherwise qualified and of good moral character.

**School Inspectors.**—At a meeting of the New York City board of health last week, one hundred and forty medical inspectors of the public schools in Manhattan and forty-five of those in Brooklyn were appointed.

**Tuberculosis among Indians.** In a recent report Dr. Sheard, medical officer of health in Toronto, says that during the past year, in the Blood Indian reserve of the Canadian Northwest Territories, in a population of two thousand there were one hundred and twenty-seven deaths from pulmonary consumption, constituting twenty-three per cent. of the total death rate. This occurred in a tribe occupying one of the finest climates of the world, among the foothills of the Rocky Mountains, a region in which consumption is extremely rare among the white population.

**The Germans and the International Gynæcological Congress.**—In our special report of the congress recently held at Amsterdam the absence of Germans is very noticeable. According to *The Scalpel* the reason for this was a personal dislike of Professor Treub, though it is scarcely credible that any body of scientific men could be so little. The congress was evidently a success in spite of the German boycott. Our contemporary implies that the loss was a gain, for it says that "the majority received the news that the German language would not be heard 'as tidings of comfort and joy,' while the *bon vivants* rejoiced, as the gastronomic feats of the Teutons are so well known at all these congresses. 'Now we shall have something left to eat and drink.' Seriously it is lamentable at the end of the century to find on an occasion of this kind a body of scientific men, especially medical men, so childish as to stay away, no matter under what provocation. The Netherland Society of Gynæcology did everything in their power to bring about a *rapprochement*. Surely the Germans did not imagine the International Congress could not go on without them! There are no indispensables to-day. If all the German gynæcologists of repute were swept away to-morrow by death or accident their places would be taken by men of other nationalities. Though Germany has done much to assist in the development of gynæcology, Germany has really borrowed more than she has herself given to gynæcology."

**Sanitation of Picnic Grounds.**—The Massachusetts State board of health is about to undertake an examination of picnic grounds and certain summer resorts relative to their sanitary condition. Special notice will be taken of water supply at different places where persons in large numbers habitually congregate, and sewerage systems will also receive careful con-

sideration. It has been observed that typhoid fever is very prevalent in September and October, a fact which it is thought may be attributed directly or indirectly to the lack of proper sanitary arrangements in crowded summer resorts.—*Boston Medical and Surgical Journal.*

**Typhoid Fever** is reported to be unusually prevalent in Paris this summer. There has been a long drought and the water of the Seine is very low.

**Navy Department,** Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending September 9, 1899. September 1st. — Surgeon E. H. Marsteller ordered to duty in connection with recruiting rendezvous, Buffalo, N. Y., to report at the New York navy yard, September 4th. September 2d. —Passed Assistant Surgeon B. R. Ward and Assistant Surgeon J. F. Chaffee are detached from the *Boston* when put out of commission and ordered home to wait orders. September 5.—Surgeon J. C. Decker detached from the *Monadnock* and ordered to the *Monocacy*, at own expense. Passed Assistant Surgeon J. Stoughton detached from the *Monocacy* and ordered to the *Monadnock*, at own expense

**The Automobile in Paris** is a death-dealing machine which was responsible for nine deaths and over forty serious injuries to riders and pedestrians in one week last month. The authorities are being importuned to place private automobiles under more severe restrictions, which will include a lowering of the maximum of speed now allowed, and the forbidding of persons to run automobiles who do not possess certificates as to their knowledge and ability.

**"The Denver College of Medicine"** is now the corporate name of the reorganized medical department of the University of Denver. The change of name carries with it no change in the relations heretofore existing between the University of Denver and its medical department, other than placing the Denver College of Medicine in a position to have an independent legal existence, enabling it to own property, make contracts, etc.

**The Grand Army of the Republic.**—At the annual encampment just held in Philadelphia, Dr. William H. Baker, of Post 5, Lynn, Massachusetts, was elected surgeon-general of the Grand Army, and Dr. Julia Shade was elected president of the Ladies of the Grand Army of the Republic.

**Scurvy on an Island.**—A steamer recently from Clipperton Island, off the Pacific coast, reports that scurvy is causing much distress there. Five men have died of the disease, and twenty-three others are afflicted with the malady. In all there are only about fifty men on the island engaged in collecting guano for shipment to San Francisco. The captain of the steamer landed a supply of vegetables and lime juice, and improvement had already set in by the time the vessel sailed.

**Vaccination Stations.**—For the accommodation of the school children in the downtown districts, the board of health has established a branch station for free vaccination in the old school building at 68 Elm Street. This action was taken to save the expense of car-fares to the multitude of children on the lower east side and of other parts of the downtown section of the city. Children residing in the uptown districts will be vaccinated at the board of health building, Fifty-fifth Street and Sixth Avenue.

**The Potomac River Water.**—A bacteriological examination of the water of the Potomac River has recently been made by the Marine-Hospital service, and a report of the results has been published. This report is accompanied by a chart of the river basin, on which are indicated the numerous stations where infective matter was found. Thirty-six points show where colon bacilli and sewerage bacteria were found between Piedmont and Washington city. In the conclusion of their report, Drs. Sprague and Kinyoun observe: "The causal relation between the impure drinking-water and this death rate is so evident that to my mind it is almost criminal negligence to allow such an easily preventable condition of affairs to longer obtain in our midst, and it can be truthfully said that just so long as the inhabitants of this district are compelled to use Potomac water in its present state of pollution, from two hundred to two hundred and fifty lives will be needlessly sacrificed annually." —*Maryland Medical Journal.*

**The Great Things that Happen in New York.** —The London papers some time ago published accounts of two marvellous surgical feats which were alleged to have been performed in this city. The first case was that of a man who was stabbed to the heart, the ribs being parted and the heart exposed. The physicians injected saline solution to replace the blood between the pulsations, and one of them rapidly passed a needle and thread through the left ventricle, and took several stitches. The patient rallied, and when the report was issued belief in his recovery is stated. The other case is that of a millionaire, who was suffering from an abdominal ailment, the nature of which was diagnosed by the patient swallowing an India-rubber bulb, covered with photographic film. When the bulb reached the stomach it was inflated. An *x*-ray exposure was then made, the bulb deflated, and then withdrawn. The result was an excellent photograph of the interior of the stomach, revealing a large tumor. *The Hospital*, from which we learn of these reports, says that the papers gave the name of the millionaire with the gastric photograph.

**Obituary Notes.**—Dr. Charles T. Robinson, of this city, died suddenly of heart disease September 10th. He was twenty-six years old, was a graduate in arts of Manhattan College and in medicine of the Bellevue Hospital Medical College in 1895. He had been in practice eighteen months. He was married only three weeks ago.—Dr. William F. Trout died at McConnellsburg, Pa., on September 7th, at the age of sixty-six years, in the sequence of amputation of the leg for gangrene. He was graduated from Jefferson Medical College in 1856, and was a surgeon in the Union Army during the Civil War.

# Therapeutic Hints.

**Treatment of Chronic Summer Diarrhœa.—**

℞ Bismuthi subgallati ..... gr. xxiv.–xxvi.
Pulv. opii..... gr. ss.
Pepsin. pulv ..... gr. vi.–xij.
M. Trit. in pulv. No. xii. S. One every four hours, alternating with the following:

℞ Hydrarg. chlor. mitis..... gr. ss.
Cerii oxalat..... gr. ij.
Sacchar. alb..... q.s.
M. Trit. in pulv. No. xii. S. One every four hours.

—Alfred Stengel, *North Carolina Medical Journal*, April 20th.

**Diarrhœa Mixture Without Opium.—**

℞ Tr. camphor ..... ʒ i.
Tr. capsici..... ʒ ss.
Tr. lavandul. comp ..... ʒ ij.
Spts. vin. gal .....q.s. ad ℥ ij.
M. S. Teaspoonful every two or three hours.

—Rex.

**Treatment of Syphilis at Finger's Clinic.—**

℞ Hydrarg. salicylat ..... 5
Paraffin. liq..... 50
S. One Pravaz syringeful in the week by intramuscular injection.

**For Nasal Irrigation.—**

℞ Sodium bicarbonate,
Sodium biborate,
Sodium chloride .....āā gr. xxx.
Sodium salicylate..... gr. xl.
Oil of bergamot ..... ♏ iij.
Listerine ..... ʒ ss.
Glycerin..... ʒ i.
Distilled water .....enough to make ℥ viij.
M

—G. Sterling Ryerson.

**Pruritus of the Scrotum.—**

℞ Hydrarg. bichlorid ..... gr. viij.
Alcohol,
Aquæ chamomil.....āā ʒ vi.
Chloroformi ..... gtt. v.
Aquæ camphor .....q.s. ad ℥ iij.
M. S. Apply as a lotion.

—Leistikoff.

**Chronic Nephritis.—**

℞ Lithii benzoat..... ʒ iiss.
Betol ..... gr. lxxx.
Sodii bicarb ..... ʒ i.
M. Div. in chart. No. xx. S. One powder twice daily between meals.

—Lemoine.

**Colic.—**

℞ Spir. ammoniæ aromat..... ♏ vi.
Sodii bicarbonatis ..... gr. xij.
Syr. rhei aromat..... ʒ i.
Aquæ cari..... ℥ iss.
M. et ft. sol. S. Teaspoonful as often as required.

Or:

℞ Tinct. asafœtidæ..... ♏ xv.
Olei cajuputi ..... gtt. ij.
Magnes carbonat..... ʒ ss.
Syr. acaciæ..... ℥ ss.
Aquæ anisæ..... ℥ iss.
M. et ft. mist. S. A teaspoonful as required.

—Larrabee.

It may be necessary to prescribe some form of anodyne to relieve the pain of the colicky attacks until such changes have been consummated in the milk as will prevent its disagreeing with the child. Occasionally, therefore, it may be necessary to give some form of opium. Of the preparations of opium codeine is decidedly the best, as it interferes less with normal digestion and peristalsis than any other form of opium medication. At the best, however, opium by its interference with the gastric and intestinal secretion tends to keep up the colicky condition, and should be used only as a last resort. The various soothing syrups, cordials, etc., usually contain opium, and should be tabooed.— Philip F. Barbour, *Pediatrics*, May, 1899.

**To Stimulate Perspiration.—**

℞ Pilocarpinæ hydrochloratis..... gr. ⅙
Mucilag. acaciæ..... ℥ iij.
M. S. Three to six teaspoonfuls a day.

—Lemoine.

**Dyspepsia with Insufficiency of Motor Action.—** Mathieu (*La Presse Médicale*, April 5, 1899) considers ipecac in small doses as one of the best excito-motors for the stomach. It can be prescribed in the following way:

℞ Tinct. ipecac,
Tinct. calumbæ,
Tinct. gentian .....āā 5 gm
M. S. Fifteen to thirty drops two or three times after a meal at intervals of from one-half to one hour.

Or:

℞ Tinct. ipecac ..... 6 gm.
Saccharin ..... 0.10 cgm.
Menthol ..... 0.25 "
Alcohol..... 40 gm.
Simple syrup ..... 120 "
M. S. Two to four teaspoonfuls in coffee after meals.

Or:

℞ Tinct. ignatiæ..... 6 gm.
Tinct. ipecac ..... 1 "
Tinct. anisi..... 5 "
M. et filt. S. Take six drops in a little Vichy after each meal.

Or:

℞ Powdered ipecac ..... 0.02 cgm.
Sulphate of potassium,
Nitrate of potassium .....āā 0.05 "
Bicarbonate of soda..... 0.30 "
M. et ft. tablet No. i. S. Take in a little water five to ten minutes before a meal.

**Catarrhal Laryngitis.—**

℞ Chloralis..... gr. lxxv. ( 5 gm.)
Potassii bromidi ..... gr. xlv. ( 3 " )
Ammonii bromidi..... gr. xxx. ( 2 " )
Aquæ cinnamomi..... ℥ ij. (62 " )
M. S Teaspoonful, and repeat in twenty minutes if not relieved. This is for a child of five years of age.

—Joseph Holt, of New Orleans.

**Tabes.**—The use of stimulant liniment rubbed well over the surface of the body has proven also of great value in stimulating circulation, so deficient in this class of patients. The following prescription has done well in the writer's hands:

℞ Ammon. chlor ..... ʒ iv.
Glycerin ..... ʒ i.
Tinct. capsic ..... ʒ ss.
Aquæ menth. pip ..... .....q.s. ad ℥ xij.
M. S. Rub on body daily for twenty minutes with massage.

—Pearse.

**Nervous Affections.—**

℞ Sod. glycerophosphat..... 25
Aq. aurantii flor.,
Aq. destillat .....āā 50
Syr. aurantii cort ..... 20
M. S. Teaspoonful three times daily.

—Kahane, *Klin. ther. Woch.*, No. 51, 1898.

**Hay Fever.**—In the treatment of hay fever two new drugs promise well—orthoform and suprarenal capsule. Orthoform will allay the sensitiveness, the hyperæsthesia, and the paroxysmal sneezing. Its effects are in duration many times longer than those of cocaine, and it has no toxic action. When we wish to give the patient free breathing through the nose and lessen the serous discharge, the use of a solution of suprarenal capsule will accomplish the desired result without the disadvantages of cocaine.—Dr. Edward W. Wright, *New York Medical Journal*, May 6th.

# Society Reports.

## INTERNATIONAL CONGRESS OF GYNÆCOLOGY AND OBSTETRICS.

*Held in Amsterdam, August 8, 9, 10, 11, and 12, 1899.*

(Special Report to the MEDICAL RECORD.)

*Second Day—Wednesday, August 9th.*

(Continued from page 314.)

**Comparative Value of Antisepsis and of Improvements in Technique in the Results of Operative Gynæcology.**—M. RICHELOT, of Paris, opened the discussion upon this topic. He remarked that a study of the subject proposed required an investigation into (1) Our operative results. Under this heading he would describe (*a*) the evolution of antisepsis, its rôle, and its limitations; (*b*) the modifications of technique in late years and its extreme importance. (2) Our therapeutic results.

Operative results: The development of antisepsis. The speaker showed how the first few years of antisepsis, the "era of credulity," of blind trust in the results of "in vitro" experiments, had gradually given place to our later methods. He signalized sterilization by heat as the one great advance; heat was our "greatest antiseptic." Nevertheless, chemical antiseptics were still necessary for the hands, the field of operation, etc. It was a great mistake to suppose, as some did, that so-called asepsis was nothing more nor less than ordinary cleanliness; we could safely aver that the continual effort to attain asepsis by every means had brought forth the most admirable results. The speaker then dwelt upon the limitations of antisepsis. Although we could, by a rigorous antiseptic procedure, avoid infecting our patients, antisepsis itself could do nothing against infection already present. For example, a pus tube, by careless handling, burst, infected the peritoneum, and carried off the patient. Certainly some such cases ended in recovery; and in such no doubt the *vis medicatrix naturæ* played a large rôle. But we should not expect too much from *natura medicatrix;* we should aid nature as much as possible. And here came in the importance of technique, the art of surgery. Where antisepsis ended, there technique began. The value of antisepsis was within narrow limits, absolute; the value of technique was relative and without limits—it depended on the operating hand and the directing head.

Evolution of technique: The great improvements in technique had been rendered possible by the use of anæsthetics, exact hæmostasis, and antisepsis.

Instruments: Among the numerous inventions under this heading that our time had produced, the greater quantity could safely be consigned to oblivion. He acknowledged the value of artery forceps and owed much to the Trendelenburg position, but, as for the rest, he did not place too much reliance on instrumental innovations. The best results were obtained by the surgeon who knew how to use his hands and his common sense. Surgical ability, in the widest sense of the term, was comprised in the three chief qualifications—dexterity, ingenuity, and judgment. Methods were becoming more and more simplified, and in that way lay progress. The successive extraperitoneal and intraperitoneal treatment of the stump, and total extirpations in the abdominal operations for fibroid, furnished a good example. Another was found in the application of "pinces à demeure" in vaginal hysterectomy. In considering the question of therapeutic results, he would once more emphasize the fact that it was antisepsis which had enabled the surgeon to perfect technique. While many operators ascribed the success of their major operations to antisepsis alone, he would like to remark upon the tendency of so many to attach, in minor operations, a greatly exaggerated importance to method and technique. He would cite as examples the unlimited number of ways of suturing the abdominal wall, and of doing colporrhaphy. Given aseptic wounds, these were largely unnecessary. To conclude, he wished to remark that the union of antisepsis with improved technique paved the way for conservative gynæcology, and that in this direction lay the progressive improvement we hoped to attain.

DR. BUMM, of Basle, said that there were two ways by which present-day surgeons endeavored to attain the ideal of an even, sure, and normal healing of fresh operative wounds. These were a close study of anti- and aseptic procedures and of improvements in technique. He would endeavor to determine the influence which each had in the success of our operations. The absolute reliance on the protective power of antisepsis had been a good deal diminished by exact investigations, as it had been proved by a whole series of experiments and observations that elimination of all micro-organisms during the operation had not yet been attained.

A year's bacteriological research made during a great number of operations from beginning to end, upon the skin of the hands as well as the operation field, the wound, the instruments, the dressing and ligature material, had given him the following results: (1) There was no way to remove with certitude all micro-organisms from the hands. The successive use of soap and hot water, of alcohol, and of a solution of lysol or sublimate, for ten minutes each, was not sufficient to sterilize the skin with certainty. For these experiments rigid precautions, as prescribed in Hälger's method, were necessary to obtain satisfactory results. (2) The same conclusion was to be drawn with regard to the skin of the rest of the body, and especially for the external genitals, the perineum, the vagina, etc. (3) During the course of the operation we found on the instruments and ligatures, and in the wound principally, the micro-organisms originating in the deeper parts of the epidermis and from the glandular ducts. In fifty major operations, under exact control, none was found entirely free from the presence of micro-organisms. (4) With the "aseptic" method, even when the operation was made in the best conditions and with the greatest precautions, the number of micro-organisms was far higher than that which was found in using the antiseptic method. At the end of the operation the so-called sterile salt solution contained regularly micro-organisms, sometimes in great number. (5) The micro-organisms of the atmospheric dust were but of small importance in the infection of operation wounds. (6) Difficult as it was to operate without giving access to the micro-organisms, it was still more so to keep them away from the wound and its surroundings for a greater length of time.

It was therefore illusory to think that either asepsis or antisepsis could bring about a sterile condition of the wounds. According to circumstances, there would be in every wound more or less bacteria. In spite of this proved presence of micro-organisms, most wounds healed without suppuration or fever. This result was due to the bactericidal power of the organism. But this bactericidal power of the organism, could be insufficient, and this occurred when the wound was brought into contact with virulent micro-organisms or when it presented bad conditions for the full development of the bactericidal qualities of the tissues and humors. This second possibility of insufficiency of the bactericidal power of the organism brought us to a point where the territory of technique overlapped that of antisepsis. Technique had to remedy the insufficiency

of our antiseptic and aseptic means; it had to arrange the conditions of the wound in such a way that the organism should be able to win the struggle against the never entirely absent bacteria. In this way it could be said that purely technical means had a great influence on the aseptic healing of wounds. For example, a short and well-conducted operation exposed the tissues for only a short time to the influence of exterior surroundings and brought manipulations to a minimum; in this, way it diminished the chances of accidental infection. The number of micro-organisms entering the wound would be a good deal less than in an operation of long duration, in which the tissues were lacerated by repeated manipulations. In addition to this, a short operation did not so much tax the resisting-power of the wounded tissues, as well as of the entire organism. To expose the peritoneal cavity during a long time had a well-known bad influence on the heart, the intestines, and the serosa. The importance of hæmostasis for the aseptic healing of wounds was universally recognized. The drier the wound, the better were the chances for primary healing. On the other hand, the blood as soon as it left the vessels lost its bactericidal properties and became an excellent medium of culture for the micro-organisms. This being especially the case with the peritoneal cavity, for abdominal operations exact hæmostasis was at least as important as exact asepsis. Next in importance came the choice of the operative route. Neither the operation per vaginam nor per laparotomiam should be condemned on principle. A last point where antisepsis and technique met was drainage, and especially drainage of the peritoneal cavity. It was an established fact that drainage, even on the greatest scale, had no effect whatever on diffuse septic peritonitis. But the case was quite different when we had local troubles to deal with, such as circumscribed abscess, extensive lacerations of the serosa, or contact of the serosa with infectious matter. In these conditions we ought not to expect more in wounds of the peritoneum than in any other wound, and therefore drainage by gauze tampons was necessary. From all this the conclusion must be that to obtain an entirely satisfactory result, antisepsis and improved technique had to go hand-in-hand. The one without the other was not sufficient. The history of intraperitoneal treatment of the stump in myomotomy furnished a good example of the importance of technique in relation to antisepsis. Antisepsis was easily learned and executed. But technicalities were more difficult to learn; they represented an art that demanded above all things a born aptitude. It was high time for instruction in surgical technique, of late much neglected for antisepsis, to be reinstated in its place of honor.

Dr. Alexander, of Liverpool, remarked that antisepsis and technique went always hand-in-hand, and that therefore it was difficult to compare their relative value. He would draw a distinction: in the early days antisepsis continued during the operation (and sometimes killed the patient); nowadays it ceased with the beginning of the operation, the point at which technique began. The lessening of mortality was due to both combined.

Dr. Robert Bell, of Glasgow, emphasized the point that rapidity was not the great thing, but rather sharp knives, so as to inflict as little damage as possible on the tissues. He thought it was of value to have a small hand, so that incisions (into the abdomen) might be smaller.

Dr. Hartmann, of Paris, discussed the improvement lately in results of abdominal operations. The decrease in mortality in his own statistics had been enormous, especially in hysterectomy. He thought it was due, on the one hand, to a more general adoption of the vaginal route; and on the other to improved technique of the abdominal route, especially in the more careful limiting off of the field of operation by compresses and the Trendelenburg posture. It was also due to a more painstaking hæmostasis, to the careful restoration of peritoneal surface, to the abandonment of the large silk ligature in tying off pedicles *en masse*, and to the substitution of asepsis for antisepsis.

Dr. Keiffer, of Brussels, simply agreed with Dr. Richelot's remarks.

Dr. Jonnesco, of Bucharest, drew the attention of the congress to the fact that in some clean cases, even with perfect asepsis and technique, there was suppuration. What was the causative factor? To him it was unknown. He thought that nowadays there was a decided tendency to exaggeration, both in asepsis and technique. Ungloved hands, unmasked mouth, uncovered moustache had never given him bad results. The tendency toward too rapid operating was reprehensible. As Schede had said, one should be a good anatomist to operate well. Some unsuccessful cases had been, he was sure, due to a lack in this respect. With regard to technique, he did not regard the angiotribe as an advance. He had used all kinds. There was too great risk of secondary hemorrhage.

Dr. Straatz, of The Hague, agreed with Dr. Bumm. He thought the main thing was to avoid infection; method imported little. Septic cases should be isolated. In one hundred and thirty clean cases, keeping septic cases away, he had had no mortality.

Dr. Doyen, of Paris, said that, granted asepsis, the success of operations depended altogether on technique. Every major operation should be simplified as much as possible, and its technique absolutely and mathematically determined. Thirdly, the surgeon should be able to appreciate, almost intuitively, the vital resistance of the patient. He then described his own methods of securing asepsis. He had not used iodoform for ten years. Its supposed good effect in tuberculosis he thought was due to the mechanical irritation of the gauze on a raw surface. In its stead he used glutol powder and glutol gauze. He was about to publish an account of experiments with a new ligature and suture material. He believed in drainage in any operation likely to be followed by much serous oozing.

Dr. Rein, of Kieff, disagreed with the statement of Dr. Richelot, "that the very best antiseptics were insufficient, as demonstrated bacteriologically." He believed we could accomplish perfect asepsis, although it was difficult.

Dr. Smith, of London, remarked that asepsis was more important than technique; the latter would be in bad case without the former.

**Cinematoscopic Exhibition.**—Dr. Doyen, of Paris, exhibited a number of cinematoscopic views which had been demonstrated for the first time last year at the British Medical Association meeting in Edinburgh. They represented a series of operations in general surgery as performed by himself. What was chiefly remarkable about the operation was the rapidity with which they were performed. A large window in the cranium was opened, and the brain was exposed in between three and four minutes from the beginning of the incision. A thyroidectomy was done in about three minutes. Hæmostasis throughout, when possible, was effected by the angiotribe. An appendectomy was done in about the same time. Other operations shown were an oöphorectomy for moderate-sized cyst, an excision of a traumatically ankylosed knee, a modified Syme's amputation, and a second craniotomy on a dry skull, showing the steps of the operation with greater clearness than in the first. Dr. Doyen called attention to the important part such demonstrations should play in the teaching of surgical technique, and

laid stress, not on the rapidity of the operations, but on the clearness with which each step could be followed by a large audience of students.

---

GYNÆCOLOGICAL SECTION.

*Third Day—Thursday, August 10th.*

**Treatment of Metrorrhagia and the Early Diagnosis of Cancer.**—Dr. Boisseau du Rocher read a paper with this title. His treatment consisted in the application, by electrolysis, of the oxychloride of silver to the uterine mucosa. It gave prompt results in cases of metrorrhagia, metritis, and in some cases of salpingitis. He used a very feeble current (4 to 10 ma.), which therefore could not possibly do harm. The process also was of great value in making an early diagnosis in uterine cancer. There were three signs: (1) Persistence of hemorrhage after several applications of the oxychloride. He could say definitely that hemorrhage arising from other causes than cancer would be arrested by his treatment. (2) The incomplete formation of the oxychloride and the defective adhesion or absence of adhesion of the silver stem of the apparatus to the uterine wall, such as occurred always in cases other than cancerous. (3) The inertia of the uterine muscle and its lack of response to electrical stimulation.

The first two signs had only a presumptive value, whereas the third had an absolute value. The union of the three gave absolute certainty of the presence of cancer.

Dr. Revnier, of Paris, related the history of a case in which the diagnosis had been very difficult; in which, indeed, he had diagnosed fibroma. The author, upon the evidence of his method, declared for cancer, which was proved by operation.

**Appendicitis in Women.**—Dr. Villar, of Bordeaux, in this paper insisted on the frequency of the relation in time between appendicular attacks and menstrual periods. Diagnosis was the important point. Appendicitis might be confounded with an inflammation of the adnexa, and vice versa, or they might coexist. He reported several illustrative cases. He insisted on prompt interference—within two or three hours of making the diagnosis.

**Experimental Investigation into Uterine Atrophy following Castration.**—Drs. Jentzer and Beuttner, of Geneva, read a paper with the above title. The experiments had been performed on ten cows, thirteen rabbits, and four dogs. In the series on cows atrophy had been constant and was most marked in the uterine musculature, this being largely replaced by fibrous tissue. It was evident both macroscopically and microscopically. The results in rabbits and dogs were similar. In six of these ovarian extract (0.1 to 0.2 gm. daily) had been injected subcutaneously, but had not prevented atrophy. The animals had been killed from the sixty-fourth to the one hundred and thirty-fifth day after oöphorectomy. In the other series similar periods were allowed to elapse before killing.

**The Use of Salipyrin in Gynæcology.**—Dr. Beuttner, of Geneva, read a paper with the above title. He reported a series of twenty-four cases. His conclusions were that salipyrin may be used with success in: (1) menorrhagia, with or without lesions of the adnexa; (2) metrorrhagia, with or without lesions of the adnexa, except in case of cancer and other tumors, and of labor or abortion; (3) hemorrhage arising from the menopause; (4) hemorrhages coming on some time after labor or abortion; (5) in threatened abortion; (6) dysmenorrhœa; (7) in uterine derangements of the nature of periodical neuralgic symptoms; (8) in menstrual pain in the absence of serious uterine lesions; (9) in conditions of psychical depression before or during menstruation.

**Vomiting of Coffee-Ground Material after Anæsthesia in Gynæcological and Obstetrical Cases, in which Instrumental or Operative Interference had been Resorted to.**—Dr. Beuttner, of Geneva, in a short paper called attention to this fact, which he had observed in seven cases, and which he had not seen elsewhere reported. In four it had followed operative interference for difficult parturition; in three, gynæcological operations. There were no digestive or cardiac abnormalities in any of the cases. The vomitus consisted of altered red cells, detritus, and mucus cells. He pointed out the necessity of differential diagnosis from cancer. In one autopsy nothing was found but numerous hemorrhagic erosions near the pylorus. Concerning the etiology he could come to no satisfactory conclusion. It might lie in the fact of the stomach being a hollow viscus, and in the peculiar arrangement of its terminal vessels. The anæsthetic had nothing to do with it. The hemorrhage might be considerable; it might occur during, immediately after, or some hours after operation.

**Resolvent Action of High-Frequency and High-Tension Currents upon Congestive Hyperplasia of the Uterus.**—Dr. Doumer, of Lille, reported two illustrative cases, one an acute hemorrhagic metritis, the other a chronic hypertrophy of the body of the uterus. He used a simple metallic hysterometer, insulated in the portion passing through the vagina by either a glass or a rubber tube. He concluded that, apart from their action on pain and on amenorrhœa (as previously noted by Dr. Maugin, of Marseilles), these currents possessed decided resolvent properties upon congestive enlargements of the uterus. Sometimes it needed only three or four applications of ten minutes each. The treatment was not only painless, but was absolutely not felt by the patient; and it produced no post-operative reaction. The technique was simple. In a series of eight cases he had had six successes and two failures.

**Abdominal Hysterectomy in Connection with Cæsarean Section.**—Dr. Carstens, of Detroit, read this paper. The author divided pelvic contractions necessitating Cæsarean section into (1) temporary, *e.g.*, by a tumor or other removable obstruction; (2) permanent—bony deformity, etc. In the first he would advise a Sänger operation; in the second a Porro. He then related the histories of six cases, four of which he had previously reported. In the technique of the hysterectomy he laid stress on the following points: (1) Chloroform should be the anæsthetic; (2) dry sterilized catgut for the ligatures; (3) the use of four clamps to control hemorrhage until the arteries could be ligatured separately; (4) no attention at all should be paid to the placenta with the idea of controlling hemorrhage. His conclusions were as follows: (1) In cases of permanent deformity requiring Cæsarean section, with a living child, the whole uterus should be removed. (2) If the child is dead before the section, the choice should be left to the parents. (3) When the patient had been in labor and the os was thoroughly dilated, complete removal, including the cervix, was indicated. (4) When section was to be done before the beginning of labor, the removal of the uterus, leaving the cervix, was the easiest method. (5) In cases in which relief could be had by an immediate or a future operation leaving normal pelves, the classical Cæsarean section should be done. (6) However, in all cases the choice of operation should always be left to the parents.

Dr. Palmer Dudley wished to make one criticism concerning the use of clamps advised by Dr. Carstens. If he was intending to do a Sänger operation and leave the uterus, he would use the ligature, because the clamp injured vessels too much. If he purposed doing a Porro, he would use the clamp. He had done

Cæsarean section three times, saving both mother and child in all. His method differed from Sänger's, and was as follows: He made a small incision, leaving a scar of five inches. He obtained perfect hæmostasis by an elastic ligature slipped over the uterus. He used constant irrigation with saline solution from beginning to end. He did not deliver the uterus till he had emptied it of the fœtus; as the child was delivered from the uterus, the uterus was delivered from the abdomen, thus avoiding any blood, etc., finding its way into the abdominal cavity. Then he turned hot saline solution into the uterus, causing contraction; he then quickly delivered the placenta and closed the wound. As to craniotomy on the living child, he would always reject it, believing that Cæsarean section, besides saving the child, was safer.

Dr. Goldspohn, of Chicago, wished merely to call attention to the transverse incision in the fundus from the points of origin of the tubes (approximately) across the fundus; a method preferred by most of those who had used it (Germans) to the longitudinal median.

**Total Abdominal Hysterectomy in Suppurations of the Adnexa.**—Dr. J. L. Faure, of Paris, read a paper with the above title. He remarked that, although the vaginal route was preferred by many in conditions of this nature, it was yet often incomplete, and frequently left fistulæ, while recurrences were common. The abdominal route allowed a complete cleaning of the pelvis, and he would advise it always in the case of chronic bilateral lesions. If the infection was acute he still advised a vaginal operation, followed later, if necessary, in the quiescent stage by an abdominal hysterectomy. He then described the technique of his own operation for total abdominal hysterectomy. He cut the uterus in the median line in halves from above downward into the vagina, the mucosa of which he then cauterized. He then dissected away each half with the adnexa from below upward, tying the arteries as he came to them. He maintained that the superiority of this operation in difficult adherent cases was evident. He presented statistics of fourteen operations of this nature with one death. Of these, five or six had been very extensive cases.

Dr. Duret, of Lille, would insist on the vaginal route for acute cases. He drew attention to a class of cases, not well known, which he would call "uterine pyæmias." In an autopsy on such a case the only lesion found had been purulent foci in the uterine wall and a suppurative phlebitis in the broad ligament. He had done abdominal hysterectomy in several such cases, which all resulted fatally; whereas in another case, operated per vaginam by morcellement, the patient had survived.

**Colpohysterotomy in the Treatment of Irreducible Uterine Inversion.**—Dr. Duret, of Lille, presented a communication on this subject. After mentioning the various methods heretofore in use, the speaker rejected hysterectomy as it sacrificed the uterus; he then proceeded to describe his own operation, which he called "posterior colpohysterotomy." It consisted in incising the posterior cul-de-sac, and then cutting open the uterus in its whole length, cervix and body, by a posterior median incision. He then simply reduced, and at the same time folded the two sides forward, so that the posterior incision lay anterior. He then sutured the uterine wound with catgut. He had obtained complete cure in three cases.

Dr. Faure, of Paris, asked Dr. Duret if he had seen what became of the broad ligaments. Were they twisted?

Dr. Duret replied that he did not know; but that probably they straightened out. The cervix, in any case, did not undergo torsion.

Dr. Dudley, of New York, maintained that we could convert any seemingly irreducible inversion into a reducible one by doing a laparotomy and dilating the cervix from within; and that this was, in his experience, much easier than was generally supposed.

Dr. Carstens, of Detroit, asked Dr. Dudley what he did with the raw surface of the fundus uteri left in such a case by the tearing of adhesions and the manipulations of reduction.

Dr. Dudley replied that he covered the fundus with iodoform gauze, and that this prevented subsequent adhesions.

**The Alexander Operation Combined with Inguinal Cœliotomy via the Dilated Internal Ring.**—Dr. A. Goldspohn, of Chicago, presented a communication upon this subject, illustrated with six drawings. He stated that the round ligaments were the only available structures which grew with the pregnant uterus and became involuted with it after labor; and that shortening them by way of the inguinal canals was the only operation whose published results after labor, so far, proved it able to stand that test. But to this end, and to make women well, more was needed than the operation as done by Alexander. A finger must be introduced through the internal ring—simply stretched—to determine the degree and effect of the shortening of the ligament; to liberate the organ when adherent, and to draw the ovary and tube into the same opening for resection frequently and for removal rarely. He then described the details of his operation (already published in the Medical Record). He had had no death in over one hundred and seventy-five total cases. One partial hernia, due to an accident five weeks after operation, existed in one hundred and twenty-five traced cases. He reported results in forty-nine consecutive cases after an average of eighteen months' observation. In six cases the women passed through normal pregnancy and labor subsequently, and in each case a normal position of the organs was found after an average period of three months.

Dr. Carstens, of Detroit, said that opening the peritoneum twice involved more risk than once; that one central incision gave a better view and was effectual; and that hernia, in Dr. Goldspohn's operation, might be more frequent when done by those less experienced than the author.

Dr. Goldspohn replied that he had never seen any complete hernia following the operation. In fact, previously existing herniæ had in several cases been cured.

*(To be continued.)*

## CANADIAN MEDICAL ASSOCIATION.

*Thirty-second Annual Meeting, Held in Toronto, August 30, 31, and September 1, 1899.*

*First Day—Wednesday, August 30th.*

The thirty-second annual meeting of the association was called to order at 10:30 A.M., Mr. Irving H. Cameron, the president, occupying the chair, and Dr. F. N. G. Starr acting as general secretary.

**Tuberculosis in Canadian Cattle and Its Prevention.**—Dr. George J. Adami, of Montreal, contributed a paper with this title. In connection with the discussion of this subject, there were three questions, he said, which were asked and had to be answered: (1) Was tuberculosis in cattle a source of danger to other cattle, so as seriously to affect their well-being and to be a source of loss to the owners? (2) If infectious from animal to animal, was it infectious from animal to man and thereby a grave source of danger to the human race? (3) If infectious from animal to man, what were the commonest modes of infection, and, as a sequel to this, how were we to diminish the danger? The answer to the first question was an unqualified affirmative. For instance, there was abundant evi-

dence in Canada that the introduction of an infected bull into a herd had been followed in a very short time by the appearance of the disease in some members of that herd. A comparison of statistics in this regard with those of other countries showed Canadian cattle in a very favorable light, and there was no country on the face of the globe that could show such favorable results as Canada. The speaker instanced the case of ninety thousand cattle subjected to inspection at Montreal in 1894, out of which number only sixty animals were rejected, and of these only two had tuberculosis to a very limited extent. He then spoke of the importance of keeping all imported cattle for breeding purposes in quarantine for seven weeks, and if, after that length of time has elapsed, they failed to react to the tuberculin test, they might be handed over to their owners. Speaking to the second question, he thought the reliable information on this subject was very scanty. Canadian cattle were singularly free from the disease. The lungs of twenty-five hundred and four animals were examined in 1894 in the abattoirs in Montreal, Halifax, and St. John, N. B., and only fourteen had any evidences of tuberculosis, *i.e.*, 0.6 per cent. It was exceedingly doubtful if any other country could show better figures.

**Results already Achieved at the Muskoka Cottage Sanatorium.**—Dr. J. H. Elliott, the medical superintendent, after an historical description of the establishment of the institution and its management, gave the results already achieved there. As discharged, the patients were classified under the terms "apparently cured," "disease arrested," "improved," "stationary," "failed," or "died." He proceeded to describe these terms and then submitted a statement of seventy-two cases discharged during the last nine months of the year ending June 30, 1899. Of these, sixty-one had bacilli when admitted and forty-seven when discharged, the average stay at the sanatorium being one hundred and fifty-two days. Twenty-five to thirty-five per cent. of those treated had no bacilli on discharge. Eighty-three per cent. of the seventy-two gained in weight, eleven and one-half pounds being the average gain. For one month, the maximum gain was eighteen pounds, and forty-three pounds the maximum total gain. Of the incipient cases, sixty-five per cent. were apparently cured, and this might have been increased to eighty per cent. with a longer stay. The time that had elapsed since the discharge of the first year's patients ranged from twelve to eighteen months. Twelve were reported apparently cured. In none of these had there been a return of the cough, and all were in the best of health.

**Christian Science.**—Dr. J. H. Richardson, of Toronto University, handled this topic without gloves. He quoted freely from "Science and Health," and, amid the hilarity of his audience, ridiculed the whole subject most unmercifully. He said it was a conglomeration of deceit, blasphemy, mesmerism, and avarice. Mrs. Eddy herself had had four husbands, and therefore, in her own personal experience, the "mental fluid" had not exerted its usual potency. He considered poverty a stern reality, not to be dissipated by the logic that "God is good."

**President's Address.**—Mr. Irving H. Cameron delivered an able and scholarly address on the subject of the overcrowding of the profession. He pleaded strongly for the elevation of the standard of matriculation, and thought that if the examiners at these examinations would only do their duty by the profession and the public the profession would not be crowded with men who were better fitted for other walks of life. He thought that too often men were allowed to slip through these examinations who had a very scanty common-school education, and that, once through, there was no means of stopping them in their medical career, as the pernicious system of allowing them to come up year after year to take one or two subjects would not prevent them from becoming practitioners, though their course extended sometimes from seven to ten years. Lack of proper respect on the part of the younger men toward the older also came in for some attention. He spoke of the undoubted honor conferred on the whole profession of medicine when, a short time ago, Her Majesty conferred the honor of knighthood upon Burdon Sanderson, Michael Foster, and Mitchell Banks; and with very perceptible sorrow he concluded his address by a reference to the death of members of the association during the past year, particularly mentioning three past presidents, Drs. J. E. Graham, of Toronto; H. P. Wright, of Ottawa; and J. H. Mullin, of Hamilton.

**An Experience in Formaldehyde Disinfection.**—Dr. F. Montizambert, director-general of public health, of Ottawa, gave the history of an outbreak of smallpox on board the *Lake Huron* steamship, twenty-six days out from port on the Black Sea, with twenty-four hundred Doukhobors on board. All of the passengers were landed on June 9th, the vessel was disinfected by the 13th, and a new crew put in by 4 P.M. on the 14th. A solution of formaldehyde was employed, and twelve ounces of this was allowed for each one thousand cubic feet of space. Two and a half months had since elapsed, and there had not been reported a single case of the disease occurring among the passengers.

**Massage and the Relief of Eye Strain in the Treatment of Glaucoma.**—Dr. George M. Gould, of Philadelphia, stated that generally all cases of glaucoma first came under the notice of the general practitioner. Four years ago he wrote concerning glaucoma that massage properly applied seemed to exert a beneficial action in stimulating and arousing normal functions generally. He illustrated this plan of treatment by citing several cases in which it had been employed with beneficial effect, and concluded by describing his method of operation. It was to be done with the soft parts of thumbs and the tips of the fingers. In this way all venous and lymph spaces were cleared and broken.

**Treatment of Acute Digestive Disorders of Infancy.**—Dr. A. R. Gordon, of Toronto, first gave a concise description of the different gastro-intestinal disorders and then dwelt more fully on the treatment and management of these cases. If the attack was a simple one the suspension of all food for from eight to twenty-four hours might be all that was necessary; water might be allowed for thirst. After this period was past, rice water and such like fluids might be permitted. Liquid peptonoids he had found very satisfactory in those of more serious aspect. It was necessary to persist in this diet for days, until all symptoms had disappeared and the child was perfectly convalescent. Cow's milk should be the very last article of diet to be allowed. Calomel with sodium bicarbonate should be early administered until the characteristic bile stools are seen, and even for some time thereafter the bowels should be watched and phosphate of soda or aromatic syrup of ginger employed to keep them in condition. In cases which become exceedingly chronic, paregoric in suitable doses may be employed.

Dr. Holmes, of Chatham, Ont., spoke of the advantages of hydrotherapy in these cases.

Dr. A. L. Benedict, of Buffalo, discountenanced opium and astringents, and said he had found catnip tea a valuable sedative to be employed.

**A Case of Subcutaneous Emphysema.**—Dr. Fred Fenton, of Toronto, reported this case, which occurred in a child of six and one-half months of age. The child had been described to the doctor as being perfectly well up to five months, except a slight attack of bronchitis about the third month. On December 23d

last, five days before death, the baby was very restless, but had no cough to any amount. In fact, cough was not a marked feature at any time. Swelling was noticed in the greater part of the neck, chest, and shoulders, passing upward over the head and face and also downward over the chest and abdomen. It was limited to the neck behind and as low as Poupart's ligaments over the abdomen. A post-mortem was made about six hours after death. The point of entrance of the air into the pleural sac could not be discovered. The spleen was large, and grayish tubercles were scattered over its surface; the liver was also large. There was no gas formation in any of the internal organs. Microscopic examination of the tissues showed tubercle bacilli in the lungs, a few in the liver and spleen, and none in the kidneys. The father, a man of fifty, had suffered from winter cough for years because of chronic bronchitis. There was no direct evidence of tuberculosis in the mother, but she was poorly nourished and looked a fit subject for the disease.

**The Successful Treatment of Three Important Cases by the Combined Form of Treatment.**—Dr. G. H. Burnham, of Toronto, recited these histories and his plan of treatment for specific iritis. Pilocarpine was employed hypodermically, from gr. $\frac{1}{40}$ to $\frac{1}{4}$, in a series of sittings, consisting of from ten to fourteen injections. An interval was then allowed to elapse of from three to eight weeks, during which time the patient was taking internally the bichloride and the iodide of potash. Then another sitting was repeated. Before each injection the patient was made comfortable in a room at a temperature of 75° F., and lay either on the left or right side as convenient. In winter a hot-water bottle was used to the feet. The proper effect of the injections was shown by perspiration and a free flow of saliva; the latter varying from six ounces to a pint. At the end of an hour the patient got up and dressed and went home. Two hours afterward he could take his food. The speaker generally gave the injection about two hours after the mid-day meal. As to the length of time this treatment should be continued there was no limit. In some a few months would suffice, while in other it was continued for three or four years. No relapses occurred in this treatment.

**The Best Method of Dealing with the Consumptive Poor.**—Dr. E. J. Barrick, of Toronto, dealt with this subject. He advocated: (1) The establishment and maintenance of rural sanatoria in connection with each municipality or group of municipalities; (2) the erection and maintenance, in connection with the above sanatoria, of suitable buildings for the reception and treatment of such advanced cases of the disease as are incapable of cure; (3) the co-operation of the Dominion government, provincial legislatures, and municipalities, and philanthropic and charitable individuals, in providing the funds therefore. Dr. Barrick spoke of the good results that had been obtained in these institutions and thought that the consumptive poor ought to be allowed to participate at the expense of the public generally.

---

*Second Day—Thursday, August 31st.*

**Skin Clinic at St. Michael's Hospital.**—There were about thirty cases shown in this clinic, and among them were several rare cases, such as dermatitis herpetiformis, larva migrans, urticaria pigmentosa, hydrocystoma, hydradenitis, favus, molluscum contagiosum, exfoliative dermatitis following psoriasis. Drs. A. R. Robinson of New York, Shepherd of Montreal, Graham Chambers of Toronto, and A. McPhedran of Toronto took part in the discussions.

**Erysipelas, with Treatment by Marmorek's Serum.**—Dr. A. de Martigny, of Montreal, stated that during the last fourteen or fifteen months he had had occasion to treat several cases of erysipelas of the face with Marmorek's serum, with very gratifying results. He described one case which proved more interesting than the others, in which tonic and general treatment had been employed for five days without any appreciable result. The temperature, which had been 105° F., with pulse rate 148, on the next morning after the injection of this serum (20 c.c.) was normal, with the pulse running at 96. Next day the pulse was normal, and in five days the patient was able to go back to her work. The previous treatment had been a thirty-per-cent. solution of ichthyol as an application, with iron and quinine internally. In addition to the injection a solution of bichloride 1:4,000 was employed externally. Other cases were cited which proved equally interesting, and the doctor then spoke of the beneficial results the antitoxin exerted in the prevention of relapses.

Dr. R. W. Powell asked for information concerning the method of injection, and if 20 c.c. was the usual amount to be employed.

Mr. Cameron confirmed Dr. Martigny's treatment, and said that he had tried this treatment very recently in four or five of his own cases with good results. He further instanced one case in which seven attacks or relapses occurred in fourteen months, but since using this treatment in that patient no relapses had occurred.

Sir James Grant, of Ottawa, said that thirty-two years ago, when this association was organized, this subject was then not even in its infancy. Since then, great advances, however, had been made, and he hoped Dr. de Martigny would prosecute his researches further in this direction. In 1860, Sir James himself received a very severe blood-poisoning and was in a very feeble state of system and near the point of death. In 1863, he was induced to try the influence of the serum of ordinary vaccine injected into his system. He further spoke of the treatment of severe cases of skin disease at that time by the same method, particularly psoriasis, as illustrating the fact that serum therapy was in vogue even in those days.

Dr. Irwin, of Weston, believed in serum therapy, and instanced a case of scarlet fever in which he gave a child 10 c.c. After two weeks, the child developed erysipelas. In twenty-four hours the disease was in a very bad stage. On the second day 10 c.c. of Marmorek's serum were injected with no result, and the child died.

Dr. de Martigny, in replying to the criticisms, stated that 10 c.c. might be sufficient in a given case providing the serum were taken from the same family of streptococci as represented in the disease, but as this was not always known, 20 c.c. was the amount best to be administered. He concluded by asking the members of the association to give this treatment a fair and impartial trial for the next twelve months, and report their results at the next general meeting of the society.

**Complications and Treatment of Fracture of the Skull.**—Dr. J. M. Elder, of Montreal, said that his paper referred to fractures at the base of the skull. During the past summer he had had seven cases of these injuries in the Montreal General Hospital, five of them being there at the same time, and all the seven cases ended in recovery. These series of cases made him study up the subject, and the good results of the routine treatment followed caused him to wonder whether we as general practitioners were not too prone to think that in this form of injury treatment was useless. He considered such an attitude quite unjustifiable, as it would be in a compound fracture of the tibia, for instance. The history of the first case cited was as follows: A young girl, aged eight years, on May 30th was rendered unconscious as the result of

a fall of fifteen feet, striking on the head. There was a large hæmatoma about the parietal bone and a depressed fracture above the left ear; the pupils were widely dilated; blood was oozing from the nose and ears. Bright red blood in small quantities was vomited, which on examination with the mirror was found to be originally dripping from the vault of the pharynx. Something had to be done at once. The left common carotid artery was immediately tied, the injury being on the left side; the patient regained consciousness on the third day, and the temperature kept fairly good. On the twelfth day she developed thromboses in different sinuses, but she fully recovered, and left the hospital, perfectly well, after a period of twenty-six days' habitation. She continued well, and was in perfect health at the present time. The histories of the other cases were given, after which Dr. Elder detailed the routine treatment to be followed. Absolute rest in bed and quiet, and attention to the mouth, nose, and ears were enjoined.

Dr. Lett, of Guelph, Ont., brought up the question of mental trouble following these injuries and whether any symptoms of this nature followed the act of tying the carotids.

Dr. Shepherd, of Montreal, mentioned that he had tied the carotid many years ago for an injury of this character. In his case, there was a gradual loss of consciousness after the accident, and then he had operated and had found a large clot at the base of the skull. The hemorrhage was so profuse that he tied the common carotid immediately. There were no mental symptoms afterward in this case.

Dr. Elder stated he had assisted Dr. Shepherd in operating on that case, and had but recently heard that that patient had become insane, which fact Dr. Shepherd, however, took occasion to deny. He was watching this case carefully to see if any such symptoms did supervene.

Dr. Atherton, of St. John, N. B., stated that he had seen the carotid artery tied in the case of a medical man of St. John and no mental symptoms followed; and if any of the members should hear him orate on a medical or political topic, he would perceive that his mental faculties were all right.

Dr. Bell, of Montreal, thought that certainly many cases could be relieved by prompt interference. We could do very little to avert the mental symptoms which were the direct result of the traumatism; but we should not let these patients die of hemorrhage. The great point was to know when to interfere, and to interfere promptly.

**Observations on Adenoids and Enlarged Tonsils and Their Removal.**—Dr. D. J. Gibb Wishart, of Toronto, in a four years' service at the Hospital for Sick Children, gave the results from 1896 to 1899 of a total of 103 operations, 47 being boys and 56 girls. Twenty-four per cent. were under five years of age, twenty-four per cent. were over ten years, and fifty-two per cent. were between five and ten years. Some of these were examined some years after operation. In only sixteen cases could an examination be obtained, and only four of these showed any return of the disease. Five of the patients had been previously operated on by other surgeons. Two deaths occurred, both from the anæsthetic. In forty-seven per cent. of the cases there were enlarged tonsils. Dr. Wishart spoke of the diagnosis of adenoids, and said that the facial expression was most helpful. The nose was flattened and broadened between the eyes. In discussing the employment of anæsthetics in these operations, he favored chloroform, nitrous oxide gas being too evanescent in its effects to prove beneficial. Ether at times could be advantageously substituted for chloroform. Tonsillotomy was too frequently performed.

Sir William Hingston had rather that Dr. Wishart had confined himself to one or the other topic because remarks on one did not apply to the other. It occurred to him that when we found these adenoids present we should operate as soon as possible. There was nothing to be gained by waiting. When he came, however, to the tonsils, that was a very different thing. He thought many operated there altogether too frequently. He had seen whole families of children with enlarged tonsils, and when they grew older the tonsils came down to their normal condition. He had seen the tonsils almost meeting, and yet had hesitated to remove them. He also took exception to the use of the spray in the nasal cavities, as the membrane of the nose was unaccustomed to it. For years he had not used water medicated in any way for use in the nose. He preferred to get there by the proper application of powders.

**Tuberculosis and Insurance.**—Dr. John Hunter, of Toronto, contributed this paper. He spoke of giving applicants for life insurance the advantages of progressive medicine and of the modern thought of the day. It was the first and most imperative duty for examining physicians to be honest for their employers. It was the duty of the physician to furnish the medical director with a full, accurate, and honest report in all cases. The purport of the paper was to invite discussion, that might be used to define more clearly "where we were at" with reference to the relationship between tuberculosis and insurance. He spoke of the causative and predisposing factors of tuberculosis, viz., environment, physical condition, and hereditary tendency. Of the latter so much stress was not now laid on heredity as formerly; the disease was infectious just as scarlet fever was infectious, only with a longer incubation period. He quoted Dr. Bryce as saying that about eighty per cent. of deaths from tuberculosis occurred among working classes or individuals working at trades.

Sir James Grant, of Ottawa, entered a strong plea for the establishment of a great national society such as that instituted by Sir William Broadbent in England, over a year ago, for the spread of information among the people with regard to this disease and the means necessary to be adopted to stay its ravages.

**Cyst of Broad Ligament.**—Dr. Charles Smith, of Orangeville, Ont., related his experience with a case of this kind. He described fully the operation he had performed for the relief of his patient, and noted the difficulties encountered in its completion. The tumor was removed through an incision five inches in length, and the patient subsequently enjoyed the best of health for five years, when she succumbed to an attack of apoplexy.

**Implantation of the Ureters in the Rectum in a Case of Exstrophy of the Bladder, with Patient.**—Dr. George A. Peters presented the patient, a little boy aged four and one-half years, who, after the description of the operation, was most thoroughly examined by the surgeons present. In addition to the exstrophy, the patient had also procidentia recti. These conditions were very troublesome, loathsome, and disgusting to friends and should be submitted to operative procedures for relief. Two years ago, Dr. Peters operated on this child for the relief of the rectal condition with very marked and beneficial results. The exstrophy had been removed altogether. The operation was performed extraperitoneally, and the ureters were conducted one on either side into the rectum. Almost immediately after the operation, the rectum manifested a tolerance for the urinary secretion. The child could now go from two to three hours without anything passing from his bowel: at night he could go from four to five hours. Dr. Peters stated there was danger of death in these cases after operation, from an ascending pyelo-nephritis. In animals on which

this operation had been performed, this was the manner of their death.

**Co-Operation of Surgeon and Physician in Abdominal Cases.**—Dr. A. L. Benedict, of Buffalo, took this as the subject of his paper, and pleaded for the co-operation of the medical and surgical attendants upon abdominal cases of tumors and cancers in which both were required in their treatment. He was of the opinion that very often the patient would progress more quickly and efficiently if the case after operation was handed over again to the medical attendant. He proceeded to instance a number of cases in support of his contention, as cancer of the cardia, etc., and asserted that we should not make a diagnosis at the time of the operation.

Sir William Hingston said the diagnosis should not be made at the time of the operation, but that by a process of exclusion it could generally be arrived at satisfactorily.

**Gall-Bladder Surgery.**—Dr. J. F. W. Ross showed a cabinet of gall stones which he had removed in operations; also a mucous fistula in a specimen of the gall bladder. He described at some length the surgical operations of the gall bladder, stating the difficulty he generally had in extracting these stones from the common bile duct. He exhibited an instrument he had devised for this procedure and had had manufactured in England, with which now he could overcome his former difficulty.

Dr. Holmes, of Chatham, Ont., stated that when the gall bladder was enlarged and the abdominal walls were thin, the operation for the removal of these stones became a comparatively easy one. He illustrated on the blackboard how he extracted the stones from the common bile duct without any difficulty.

**Address in Surgery.**—Dr. W. B. Coley, of New York, delivered an able and classical address on the radical cure of hernia. He traced the rise and progress of the operation from the earliest times, mentioning the names and dates of those who had anything to do with improving or perfecting the operation. He then discussed the operation as performed at the present day and noted the rapid progress brought about within the last decade, apportioning to Macewen, Bassini, Kocher, Halsted, and others, the respective honor that should be allotted to these gentlemen. Then a description of their operations was given, and with a reference to femoral and umbilical herniæ he concluded his subject.

---

*Third Day—Friday, September 1st.*

**Anæsthesia by Chloroform and Ether.**—Dr. W. B. Jones, of Rochester, described this subject in detail. The anæsthetist was to give his whole attention to the work in hand and take notice of nothing pertaining to the operation. He should be a thorough master of the subject and should countenance no interference on the part of the operator. The preparation of the patient for an operation was quite completely gone into, and then the essayist proceeded to touch on the physical condition of the subject. Referring to the heart, it was not so much heart murmurs that one had to fear as it was a degenerated state of muscular fibre. The capacity of the chest should be understood, and the total quantity of solids excreted in the twenty-four hours, by the secretion of the kidneys, should be known. Attention was then given to the quantity of the anæsthetic, from eight to twelve drops per minute being sufficient to keep the patient anæsthetized. Everything should be close at hand, so that in the presence of an emergency or pending dissolution, prompt service could be rendered. In conclusion, he said the anæsthetist should have a knowledge of the operation that was about to be performed and the length of time that ought to be consumed therein.

**Some Observations on the Treatment of Cancer.**—Dr. A. R. Robinson, of New York, gave his views concerning the epitheliomata, and illustrated by means of a diagrammatic drawing the cases of cancer in which the knife was indicated. He considered that in those cancers in which one could not cut down deeply, as on the scalp and around the nose, an arsenious acid paste was preferable. The composition of this paste should be equal parts of arsenious acid and gum acacia of the consistency of butter. It should be applied and left on from sixteen to eighteen hours to get the right effect. From this would result a complete necrosis *en masse* and an inflammation, but a simple one, with resulting granulation. The speaker took exception to a recent remark of Mr. Watson Cheyne, that all these cancers should be treated early with the knife, and the knife alone. This was an assertion too sweeping in its character.

Dr. Shepherd thought that in the majority of cases the knife was the proper instrument, but in cancer on the scalp or at the side of the nose, escharotics if properly applied were better than any other remedy. Cancer in the first place was local and ought to be treated immediately by removal.

**Dominion Registration.**—Dr. Roddick had this subject in hand, and in an able and exhaustive speech on the whole subject presented the matter in its proper light to the members of the association. The plan or scheme as outlined by him was as follows: There was to be a central board, called the Dominion Medical Council. Each province would have three representatives on that board: one nominated by the governor in council, one appointed by the Provincial Medical Council, and the third the president of each provincial council *ex officio*. All practitioners of ten years' standing in any one province would be, should they so desire, licensed by this Dominion Council to practise in any of the other provinces, but no practitioner would be so licensed until he was a licentiate of ten years' standing. The provincial medical councils were to remain and go on doing their work as in the past. The Dominion would look after the licensing of young practitioners when they desired to practise in any province they pleased, and as aforesaid.

Dr. Arthur Williams, of Ingersoll, Ont., representing the Ontario Medical Council, supported this plan in a strong speech, and at the conclusion moved a resolution indorsing Dr. Roddick's scheme and further authorizing that gentleman to proceed to Parliament at the next session and bring about the consummation so much to be desired.

Dr. McNeill, of Prince Edward Island, seconded the resolution, and numerous other gentlemen supported it, after which it was put to the meeting and carried unanimously.

**Notes on Recent European Conventions.**—Dr. R. A. Reeve, of Toronto, detailed at some length his experiences at several of these meetings this summer while in Europe, at the British Medical, the International Otological, and the International Ophthalmological congresses. He reviewed several of the papers and addresses which he had heard, and spoke of the newer remedies of the silver salts, such as protargol and argentin, which are proving more effective and less irritating than nitrate of silver in conjunctivitis, etc.

**Surgery among the Insane.**—Dr. A. T. Hobbs, of the Asylum for the Insane, London, Ont., read a paper on this subject. He spoke of the essential differences in operating on persons in their right senses and on these unfortunates. The difficulties of securing examinations, especially in women, were dwelt upon, and the large proportion of insane women having pelvic

disease called for immediate attention. Statistics of cases and operations were given, and the percentages of recoveries and improvements. The best results accrued from inflammatory diseases of the pelvic organs when operated on; the operations for perineorrhaphy were not followed by such good results. Ether was always employed as an anæsthetic; chloroform, having proved weakening after operation, was abandoned.

Dr. Ernest Hall, of Toronto, gave it as his opinion that ninety-two per cent. of insane women had pelvic disease.

**Craniectomy for Microcephalus.**—Dr. W. J. Wilson, of Toronto, read a paper with this title, and presented the patient, a boy aged four and one-half years. Before operation, all the child could say was "mamma." In a very short time after the operation, he could say many words and was progressing rapidly. He seemed also to have a good musical ear. He also became straight and erect; previous to the operation he had walked with his body bent forward almost at a right angle.

**The Election of Officers** resulted in the choice of the following: *President*, R. W. Powell, of Ottawa; *Vice-President* for Ontario, Dr. A. J. Johnson, of Toronto; *Vice-President* for Quebec, Dr. A. R. Marsallais, of Montreal; *Vice-President* for New Brunswick, Dr. Meyers, of Monckton; *Vice-President* for Nova Scotia, Dr. W. G. Putnam, of Yarmouth; *Vice-President* for Prince Edward Island, Dr. S. P. Jenkins, of Charlottetown; *Vice-President* for Manitoba, Dr. W. J. Neilson, of Winnipeg; *Vice-President* for Northwest Territories, Dr. Hugh Bain, of Prince Albert; *Vice-President* for British Columbia, Dr. O. M. Jones, of Victoria; *Treasurer*, Dr. H. B. Small, of Ottawa; *General Secretary*, Dr. F. N. G. Starr, of Toronto.

In 1900 the association will meet in Ottawa.

## Correspondence.

### OUR LONDON LETTER.

(From our Special Correspondent.)

SUMMER MORTALITY—ALLEGED INCREASE OF LUNACY—THE GOVERNMENT LABORATORIES REPORT—A HEALTH EXHIBITION—PRIZE DUST CARTS—A BOGUS PATIENT—A FOOLISH RUMOR ABOUT PLAGUE.

London, August 25, 1899.

Another heat wave has been passing over us, and although our temperatures do not reach such as you experience, they have considerable effect on the majority and make a difference in the mortality. Meteorologists are warning us to expect more sultry and oppressive days, to continue until perhaps thunder storms bring about other conditions. The thermometer has been rising about four degrees daily, until yesterday 88° F. was reached in the shade, and to-day seems hotter, so we are likely to pass 90° F. In the country 75° to 80° F. has been a frequent record, but in other places this has been exceeded, and harvesting has been almost arrested by the difficulty of working in the full sunshine. Cases of sunstroke are reported from various quarters, and we have had them in London streets. The usual increase of diarrhœa under such circumstances has had a decided influence on the mortality.

The registrar-general's returns, published in the papers yesterday, show that in the week ending the day before, the death-rate of the great towns had gone up to 25.7. The highest point reached through the whole of last year was 24.6, the point touched again a fortnight ago. In as many as twenty-eight towns the mortality exceeded 20, and in eight of them 30. Among these may be noted: Manchester, 30.3; Plymouth, 30.6; Liverpool, 31.8; Portsmouth, 32.5; Brighton, 33.9; Bromley, 38.3. The number of deaths recorded in London was 2,208, an excess of 473 above the average. Most deaths were due to zymotic and abdominal diseases, and nearly fifty per cent. were those of infants. Here the effect of infantile summer diarrhœa is obvious.

The long-continued dry weather is also having a serious effect. In many villages there is scarcity of water. The rainfall of June and July was far below the average—only one and three-quarters inches, against four and one-half inches. The present month so far has given only one-tenth inch, while the thirty years' average for the whole month is one and three-quarters inches. With only six days to add, we can hardly get the average unless by another August flood, and, unlikely as that seems, we never know what weather to expect for days ahead.

The alleged increase in lunacy is again exciting attention, and the report of the commissioners just issued gives figures which lend some support to those who regard it as a fact. An increase of 3,114 patients certified as insane during the year 1898 is the largest increase yet recorded in any year. Of these, 2,868 are pauper patients, 231 private patients, and 15 criminal lunatics. The entire number of insane persons in England and Wales is recorded as 105,086. These figures certainly afford food for reflection from both a medical and economic aspect. Another point is, that while the numbers in public and private institutions has steadily increased, the rate of recovery has decreased, being lower for 1898 than for the average of the last ten years. The recoveries during the year bore to the average number of daily patients the ratio of 9.06 per cent., and to the total number of patients under treatment 7.39 per cent. Further, the recovery rate has been falling regularly during each quinquennium since 1873. The numbers in asylums and license houses increased more rapidly than those maintained in workhouses or with relatives. This fact accounts to some extent for the continual increase in the demand for accommodation in asylums, leading to the construction of fresh buildings at enormous cost. There are tables in the report showing the assigned causes of the insanity of those patients admitted during the year, but, as the commissioners have pointed out in former reports, the figures cannot be regarded as altogether trustworthy, as they are based on information obtained from friends and other persons. Hereditary influence is named as the cause in 20.4 per cent. of the men and 25.9 per cent. of the women; intemperance in drink, twenty-two per cent. of the men and 9.1 per cent. women. It is probable that intemperance is really accountable for a considerably larger percentage, the tendency to attempt concealment of this vice being great, and its secondary consequences being sometimes overlooked.

The report of the work of the government laboratories for the year ending March 31st has just been published. The samples of food and drugs dealt with were more numerous than for several years past, but there are fewer instances in which the chemists differed in their conclusions from the public analysts. It would appear that the government was guided a good deal, in framing the new act, by the opinion of Professor Thorpe, the chief of the government laboratories, on questions relating to dairy products and on standards of purity. The professor has been appointed on the departmental committee concerning preservatives and coloring matter, and this committee will begin its work in October. During the year fifty-seven samples of tea, representing sixteen hundred and six-

teen packages, were refused admission in consequence of being adulterated or containing leaves which had been exhausted. Out of one hundred and fifty-eight samples of tobacco one hundred and thirty-two were pure and twenty-six adulterated, but the adulteration had not taken place in this country. Penalties were obtained in one hundred and fifty-seven cases for adulterating beer by watering. Lime juice and lemon juice were generally found of good quality. Experiments have shown that butter may give the reactions for cotton-seed oil when the cows had been fed upon cotton cake. Much of the work this year was carried out for the Home Office, on the use of lead glazes and phosphorus.

A very successful health exhibition has been held at Lincoln, at which twenty-three thousand people passed the turnstile, and yet hundreds more were turned away.

The London County Council offered a prize of £25 for the best design for a covered dust-cart, and a selection has been made, so that there is some hope that the nuisance of the old cart will shortly be abated.

Last week a bogus patient was concerned in an attempt to rob a surgery. His confederate attempted to lift convenient articles while the doctor was being consulted. The bogus patient prevented the doctor from going to investigate a suspicious noise, so the thief escaped, but the sham patient was promptly handed over to the police.

A rumor has been widely circulated for two or three days that plague had appeared in a London hospital, but there was absolutely no truth in the report, although some veracious evening papers did not hesitate to assist in its circulation.

## AN INTERNATIONAL LANGUAGE FOR SCIENTIFIC MEN.

To the Editor of the Medical Record.

Sir: The article of Dr. R. Ellis with the above heading, in your issue for September 2d, naturally enough interests me. All I could say about it, however, would only be a repetition of what I have said already. I only wish to ask Dr. Ellis to accept a few remarks about learning a language. The way of teaching languages as it is practised now in general should be interdicted by the authorities or by the societies against cruelty to children. In reality it is the easiest thing for anybody, even not talented, even not otherwise highly educated, to learn quite a number of languages, and all of these so equally well that nobody can distinguish which of these languages is the mother tongue. A German peasant girl, employed by me to do the general housework, had in comparatively short time learned to speak Greek most fluently, simply by being around my little daughter and her Greek governess. Many years ago I had an Irish servant girl, who had been around the children in a Belgian family who lived in New York. When she happened to open the door for French patients of mine the latter were at a loss how to place her, because she spoke French in most refined manner without foreign accent and her appearance was that of a modest houseworker. My little daughter, now eleven and one-half years of age, has learned to speak, to read, to write Greek, French, and English, all in New York, and all without the faintest shadow of an idea of exertion, much less torture. It is impossible for anybody to say which of these three languages is her mother tongue, whether one hears her speak or read, or sees her writing. She speaks German also, but this language she shall learn better later on. Examples of everyday people, mechanics, laborers, speaking three, four, or even more languages you can often meet in the Levant. In New York you can learn as many languages as you like without teacher, without book. I have a method, and one time I thought I was the inventor of this method, but later on I learned that I could not take out a patent because the celebrated Schliemann had invented it before me. But surely Dr. Ellis is quite correct, and there is no exaggeration possible: the learning of a language by the present school methods is an impossibility.

A. Rose, M.D.

## A REAL CHARITY—A TRIBUTE TO THE LATE DR. CRAMPTON.

To the Editor of the Medical Record.

Sir: By special dispensation I was permitted to visit Sea Breeze, the Coney Island summer home which is conducted by the Association for Improving the Condition of the Poor of New York. Practically this is an institution—to use a Hibernicism—"upon which the hand of man has never set foot." Children and their mothers are its exclusive visitors. Men are not allowed within its precincts, except for lunch on Sundays.

Some fifteen years ago parties were organized and sent down by the boat, and the portion of the beach upon which the buildings called Sea Breeze now stand was rented by the association and put to their use. There were then upon the beach a few low structures, just sufficient to keep off the rain and to make lunching pleasant and comfortable. In time the land was bought and the present very graceful buildings were put upon it. Dr. H. E. Crampton, who died in June of this year, had been a very active member and officer of the Association for Improving the Condition of the Poor. He did much to alleviate suffering and to help mankind, and Sea Breeze is an institution with the growth of which he was especially identified and the success of which was in great measure due to his efforts.

The superintendent of the establishment is Mrs. Hartshorn, a lady with white hair, a fine face, and a soft voice, in whose sympathetic spirit and in whose great though quiet and unobtrusive energy are to be found the reasons why the institution is so excellently conducted. The visitors are made at home for one week or ten days or two weeks. There are accommodations for two hundred and twenty-five. Just now some twenty more than that number sleep within its hospitable walls. Besides these there are "day parties" of five hundred, who take the steamboat down and spend the day, leaving for home at four. The youngsters having slept, the boys in one room, the girls in another, each on a mattress upon a bed all to himself (a probably unusual experience), are up anywhere from daybreak to six o'clock. The boys and girls have separate washrooms and each has a separate towel. And to each is given a tooth-brush, which is to be taken home at the end of the visit. Soon there is breakfast. Then the children play upon the sand until eleven, when the "day party" arrives. Then everybody has dinner. At two everybody, great and small, goes into the water. In the evening there is supper, after which comes the dance. This dance is "a cheering sight to see." In one corner of a good-sized hall there is a piano, upon which on the occasion of my visit a girl twelve years old played very creditably "My Pearl is a Bowery Girl," "The Sunshine of Paradise Alley," etc. On the floor were nurses in white duck uniform, dancing with the "kids," some of whom were hardly able to walk. Among these nurses was an exceedingly comely young woman whose countenance, as she danced, beamed with enjoyment, all the more, no doubt, for the reason that she has decided shortly to make an Episcopalian clergy-

man a hopeless optimist for the rest of his days. Intermingled with the visitors were the laundresses and the cooks and those who scour the floors, all in the distinctive dress prescribed by the institution. Women rotund of form, old women, and young women danced with little boys and girls, and these latter with each other. Mothers danced while their gurgling infants were held in the arms of grandmothers who stood at one side or sat on the benches along the walls. These last, many of them bespectacled, looked upon the dance with great enjoyment. Some among them had white hair and fine features which would have illuminated Rembrandt's canvases—"the justified mothers of men," as Walt Whitman wrote of such.

Presently the twelve-year-old got tired and gave place to a nurse. All around the room to alternating waltz and two-step they danced.

> "What though no rule of courtly grace
> To measured mood had trained their pace."

These good people, who came from Mulberry Bend and Bleecker Street and the regions adjoining the Bowery, danced as if their lives depended upon it. With happy faces and muscles quivering with enjoyment, they rollicked in a manner delightful to see.

Thus for a brief season do these women forget poverty and suffering, and drunken husbands, and all the rest of it.

It appeared to me that although many pseudo-charities afflict this city, here is one of those charities which really do help the deserving poor. And I thought it would be fitting if in memory of Dr. Crampton there were placed in the hall of Sea Breeze the legend which is to be found in St. Paul's to commemorate the work of another man: "If you seek his monument, look about you."

JOHN B. HUBER, M.D.

NEW YORK, September 1, 1899.

## ORRHOTHERAPY IN YELLOW FEVER.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I have very attentively read Dr. A. H. Doty's report of a case of yellow fever treated with his recently introduced serum, and I cannot help being surprised that the curing of such a mild case of the disease could be attributed to the serum, when we know that such cases require little or nothing besides keeping the bowels open, an enema or two daily, boiled or Vichy water, a little alcoholic stimulation, and a most rigorous diet during the second and convalescing stages. At least such cases as the one described by Dr. Doty would be considered in Vera Cruz, Córdoba, and intermediate points, where the disease is raging now, especially Paso del Macho and Atoyac, as very mild. The only unfavorable symptom was the large amount of albumin in the urine on the second or third day of the disease, which is always of bad omen.

The description, so carefully given, of the case corresponds exactly to the course of a mild one, in which all the symptoms decline during the third or fourth day and convalescence sets in, even when black vomit and melæna exist, the latter being almost the rule in about thirty cases attended by me during the week ending August 28th.

Without wishing in any way to detract from the merits of the serum, I am forced to confess that the case described by Dr. Doty cannot be considered a fair one on which to try the serum; and that so far, taking into account its failure in Vera Cruz, there is but little, except the hope that in the near future it will do what it is expected to do, to justify us in using it to the exclusion of the other means of treatment at our command.

Dr. Doty's remarks about judicious nourishment and stimulation before it is too late for their administration to be of any value are certainly worthy of notice, and his advice should be followed whenever practicable; unfortunately, though, in practice and here at least, neither the stomach nor the rectum lends itself well to the administration of nourishment. The vomiting and diarrhœa are as a rule so persistent that all attempts at feeding by either route, except in very mild cases, are almost useless.

F. RAMIRO DIAZ, M.D.

PASO DEL MACHO, VERA CRUZ, MEXICO,
September 1, 1899.

## Medical Items.

**Contagious Diseases—Weekly Statement.**—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending September 9, 1899:

| | Cases. | Deaths. |
|---|---|---|
| Tuberculosis | 163 | 159 |
| Typhoid fever | 70 | 21 |
| Scarlet fever | 57 | 2 |
| Measles | 64 | 9 |
| Diphtheria | 130 | 26 |
| Laryngeal diphtheria (croup) | 7 | 2 |
| Cerebro-spinal meningitis | 0 | 0 |
| Chicken-pox | 2 | 0 |

**Whooping-Cough.**—As whooping-cough is a disease which is eminently amenable to simple treatment when its acute stage has passed, mothers and nurses should be made to understand that in its subacute stage it is mainly a nervous paroxysm which, like that of St. Vitus' dance, can be cured without much difficulty by almost any treatment that will divert the patient's attention from the recurrence of the spasm, especially by the inhalation of any pungent odor such as that of ordinary smelling-salts.

**Paris Hospital Accommodation.**—Great influence is being brought to bear upon the municipal authorities of Paris to induce them to sell the grounds and buildings now occupied by the hospitals of that city and move these institutions outside the city walls, leaving nothing but emergency stations. The total value of the ground now occupied by the hospitals amounts to 166,000,000 francs. The most valuable piece of land is that of the Hôtel Dieu, 200 francs per square metre. —*The Sanitarian.*

**A Rare Obstetrical Accident.**—Mallins reports in *The Lancet* for August 19, 1899, the case of a primipara who had early in pregnancy exhibited a tendency to eclampsia and who had already had two slight "stoppages." The os being fully dilated, chloroform was administered and the forceps applied. The blades slipped over the head with the greatest facility, but the handles could not be locked, the upper blade refusing to coapt with its fellow notwithstanding the most careful manipulation. After several failures it was decided to withdraw the forceps and reapply them. The lower blade came away easily, but on attempting to extract the upper it was found impossible to do so for more than a certain distance. On seeking for the cause of the difficulty the tip of the blade could be felt to be wedged between the head and a much smaller body of an equally firm nature. Any traction on the handle only served to bring this smaller body lower down and increase the impaction of the blade. As the pains were strong and regular and the head was steadily descending, the further progress of the case was left

to nature, the handle of the imprisoned blade being merely guided in the right direction. As the delivery of the upper shoulder and arm followed that of the head, the tip of the blade came into view resting in the bend of the elbow, the hand and forearm having, through some extraordinary mischance, slipped through the fenestra of the blade. The arm was for some days deficient in power as a result of the accident, but it underwent steady improvement.

**Scarlet Fever in India.**—The *Journal of Tropical Medicine* says that the *Indian Medical Gazette* has since 1870 collected a considerable amount of information regarding the prevalence of scarlet fever in India. Up to that time it was believed that the disease was unknown in that country. Col. Kenneth Macleod, writing to the *Journal of Tropical Medicine* on the matter, comes to these conclusions: (1) That scarlet fever has been frequently imported by troop ships and that small epidemics have thus arisen among Indian natives in children. (2) That these epidemics have always been of a limited kind and have speedily died out. (3) That they appear to be more substantial and protracted in hill stations than on the plains. (4) That cases and groups of cases have been observed the origin of which could not be ascertained. (5) That the disease does not appear to prevail epidemically among indigenous races and populations.

**Decline of the Birth Rate in Great Britain.**—Dr. Henry May, writing on the decline of the birth rate in England and Wales during the past twenty-two years, concludes as follows: "The depopulating effect of these low birth rates is neutralized to a considerable extent by an accompanying decline in the death rates; but it would have been more satisfactory to have been able to regard the many lives saved and prolonged by local and general sanitary measures as a clear surplus gain instead of as a partial set-off against other lives allowed to lapse. The default of two hundred thousand births per annum may not be considered any cause for regret in the struggle for existence, but the year 1876, from which this fall dates, marks an epoch. If not "one of the stages on the road of the nation's history," it ushers in such an alteration in the relation between births and population as will considerably modify the nation's future, but one for which different counties and towns have a widely varying amount of responsibility.—*Public Health.*

**Shakespeare and Sanitation.**—An amusing paper entitled "Shakespeare and Sanitation" was read at the annual provincial meeting of the Incorporated Society of Medical Officers of Health, at Stratford-on-Avon, in July. Among other things, the author related the following: "It is interesting to find that the name of John Shakespeare, the father of the poet, first appears in the records of the municipality as owing a fine of twopence for having made a dirt heap with his neighbors Adrien Quincy and Henry Reynolds in Henly Street, and on another occasion he 'stood amerced' in fourpence for failing to keep his gutter clean."

**The Metric System** as a standard of measure has now been established for 100 years in France. It was on June 22, 1799, that the corps législatif of the fourth Messidor legalized the metric system of weights and measures in that country. A letter has been sent out by the Paris inspector of weights and measures warning pharmacists that they must fully adopt the metric system without delay and entirely give up the use of the old methods of weights and measures. The adoption of the metric system has become almost universal and is used in all scientific work even in England. In the new edition of the British Pharmacopœia the quantities of drugs are expressed in terms of grams and cubic centimetres. With the abolition of the many confusing and barbarous systems of weights and measures in use in England and the substitution of the metric system commercial transactions of Great Britain with other countries would be greatly facilitated.—*British Food Journal.*

**Scarcity of Water in Paris.**—A water-famine scare has recently added to the troubles in Paris. It is stated that leakages have been discovered in a large pipe conducting water from the river Varne. Fortunately these are now stopped up, but before this could be accomplished the reservoirs had been robbed of 45,000 cubic metres of water. The latest news states that the repair of the Varne pipe will prevent recourse to taking water from the Seine.—*Sanitary Record.*

**The Wettest Place in the World.**—Cherrapunji, in Assam, northeast of Calcutta, has the reputation of being the wettest place on the earth, the average annual rainfall being 498.15 inches, while it has the record of one month in which 147.17 inches fell. This year it seems bound to beat all previous records, 267.84 inches of rain having fallen between January and the middle of June, five months and a half, while 73.79 inches, over six feet of water, fell in a single week.—*Scientific American Supplement.*

**Treatment of the Pauper Inebriate.**—Dr. L. D. Mason writes as follows in the *Journal of Inebriety:* (1) The pauper inebriate should be recognized as a ward of the State, and his control, care, and maintenance should be provided for by the State. (2) The inebriate should be isolated and treated as a distinct and separate class in the same manner that the insane and criminals are so separated and classified. To place an inebriate in an insane asylum in his weak mental state frequently bordering on insanity, and subject him to the sights and sounds of a lunatic asylum, would be to precipitate him into a state of insanity. To place the inebriate in the jail or penitentiary would be to fix upon him unjustly the indelible stain of criminal.

**Climate of the Hawaiian Islands.**—Dr. Lyon says that the climate anywhere in the Hawaiian Islands near sea level, even in localities where the rain is excessive, is dry rather than humid. It is rarely that the air contains less than one-half the moisture it is capable of holding in invisible form. A relative humidity exceeding ninety per cent. is equally rare and is experienced only during rain storms. One can tell what is the relative humidity very nearly by observing the altitude of the clouds as they hang over the mountain. It is seldom there is anything approaching a fog at sea level. The statistics of relative humidity show an average for the year 1894 of 64.4 per cent. at midday and 78.9 per cent. at night. The figures for February were: mid-day, seventy-two per cent; night, eighty-three per cent. For August: midday, fifty-eight per cent; night, seventy-six per cent.—*Scientific American Supplement.*

**Fainting Women No More.**—Stephen Gwynn, in *The Cornhill* for July, has an article on the decay of sensibility, and contrasts life as it is now with life as portrayed in the novels of Miss Austen. He says: "My object is merely to point out the total disappearance of one quality, so well marked in Miss Austen's day that it gave a title to one of her books, yet now, in so far as it concerns its outward manifestations, nearly extinct as the dodo. I mean, of course, what was called sensibility, the attribute which used to display itself by rapturous joy, by copious tears, by hysterics, and principally by fainting fits upon the most

inadequate occasions. The change is so marked that one inclines to ask one's self whether the physical constiution of woman be not altered within the last half-century. The modern young woman does not swoon promiscuously. . . . A virago can scold and a minx can endure to be scolded nowadays without either hysterics or a fainting-fit resulting. Tears still flow freely, but woman as a rule is not proud of them. On the contrary, a young woman, I believe, will generally apologize for 'making such a fool of herself.' It is no longer considered to be an attraction or even an amiable weakness to be so feminine as all that."

**How Coleridge Acquired the Opium Habit.**—The following has been often quoted, but it cannot be too widely known. It is an account in Coleridge's own words of how he was led into the fatal habit of using opium: "I wrote a few stanzas twenty-three years ago, soon after my eyes had been opened to the true nature of the habit into which I had been ignorantly deluded by the seeming magic effects of opium in the sudden removal of a supposed rheumatism, attended with swellings in my knees and palpitations of the heart and pains all over me by which I had been bedridden for nearly six months. Unhappily among my neighbor's and landlord's books were a large parcel of medical reviews and magazines. I had always a fondness (a common case but most mischievous turn with reading men who are at all dyspeptic) for dabbling in medical writings; and in one of these I met a case which I fancied very like my own, in which a cure had been effected by the Kendal Black Drop. In an evil hour I procured it; it worked miracles—the swellings disappeared, the pains vanished; I was all alive, and all around me being as ignorant as myself, nothing could exceed my triumph. I talked of nothing else, prescribed the newly discovered panacea for all complaints, and carried a bottle about with me, not to lose an opportunity of administering instant relief and speedy cure to all complainers simple and gentle. Need I say that my own apparent convalescence was of no long continuance; but what then?—the remedy was at hand infallible. Alas! it is with a bitter smile, a laugh of gall and bitterness, that I recall this period of unsuspecting delusion, and how I first became aware of the maelstrom, the fatal whirlpool, to which I was drawing, just when the current was beyond my strength to stem. The state of my mind is truly portrayed in the following effusion, for God knows from that moment I was the victim of pain and terror, nor had I at any time taken the flattering poison as a stimulus or any craving after pleasurable sensations. I needed none; and oh, with what unutterable sorrow did I read the 'Confessions of an Opium-Eater,' in which the writer with morbid vanity makes a boast of what was my misfortune, for he had faithfully and with an agony of zeal been warned off the gulf and yet wilfully struck into the current. Heaven be merciful to him!"—*Hutchinson's Archives of Surgery.*

**Word-Blindness.**—Mr. Jonathan Hutchinson says, in his *Archives:* "An interesting example of partial inability to read, or what has been called word-blindness, has been for some time under my observation. The patient is a young man of great intelligence, upon whose education no expense has been spared. I put into his hand a page the first sentence of which chanced to be "The power of the Franks was eaten up by the civil war." After much puzzling he read out, "The power of the Franks was—by the civil war," leaving a blank, but he could make nothing of the words "eaten up." When I suggested them he said he understood their meaning perfectly, but that he had not been able to read them out because he could not spell them. Anything that is told him he can understand, but in spite of great painstaking he cannot read to any profit. In association with this defect he has complete paralysis in the right hand of the extensor secundi internodii pollicis."

**Plague in London.**—In a recent number of the London *Saturday Review* is an article dealing with the likelihood of the plague reaching England, and discussing the question as to whether the sanitary arrangements of London are in a sufficiently effective condition to preclude the possibility of its gaining a foothold there. A sketch is also given of the state of hygienic affairs in old London at the time when the plague was raging. The writer says: "We find in the days of modern sanitary reform a considerable difficulty in realizing the vast opportunities given to filth-living microbes in older London. The personal habits of most of the population were not cleanly; the water supply and the drainage were extremely defective. Great houses had cesspools of immemorial antiquity underneath them; the Thames was lined by public latrines, and the Walbrook, the record of which in plague statistics is notorious, was similarly provided. It was little wonder that as soon as the plague got to London it established itself until practically only those who were naturally little susceptible to the disease were left. Just as the plague spread from house to house rather than from person to person, it became associated with particular ships rather than with the crews or passengers, and we are better able to judge of the insanitary conditions of the ships of the seventeenth and earlier centuries from what it is still possible to see on smaller merchantmen and tramp steamers."

**Health Reports.**—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended September 2, 1899:

SMALLPOX—UNITED STATES.

### THE LEGAL VERSUS THE SCIENTIFIC TEST OF INSANITY IN CRIMINAL CASES.[1]

BY CARLOS F. MACDONALD, A.M., M.D.,

PROFESSOR OF MENTAL DISEASES AND MEDICAL JURISPRUDENCE IN THE UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE; EX-PRESIDENT OF THE NEW YORK STATE COMMISSION IN LUNACY.

THE protection of life and property, so far as it can be effected by statutory enactment, requires that offences against either one or the other, when proven, shall be visited with punishment, regardless of the social rank or station of the offender. But occasionally it happens that crimes against life, and also against property, are committed or attempted by persons suffering from mental disease or infirmity; and the law, in recognition of this fact, very properly provides that an accused person when brought to trial may plead irresponsibility on the ground of insanity or mental unsoundness. Such being the case, it becomes pertinent to examine the so-called legal tests of insanity as applied to criminal cases, in order to determine how far such tests accord with the facts of nature as interpreted by medical science. Aside from questions of responsibility for crime, the criminal law does not specially concern itself with the subject of mental disease.

In view of the fact that the right to plead insanity as an excuse for crime is recognized in the criminal code of every civilized State and country, it necessarily follows that, whenever this plea is offered in defence, the mental status of the defendant must be taken into account and the question of responsibility must be determined, either by the application of the so-called legal test or by means of competent medico-psychological testimony. The plea of insanity as an excuse for crime rests on the supposition or allegation that the accused is a victim of a form of disorder the existence of which, if established, renders him irresponsible for his acts. This being true, we may properly assume that, medically speaking, insanity and irresponsibility are so closely allied that they are essentially convertible terms, and that, whenever the existence of insanity is clearly established, the question of responsibility is practically determined. Hence this question of responsibility for criminal acts is, strictly speaking, a medical one, and it can be determined — especially in complex and obscure cases — only by those who are practically familiar with the symptoms of mental derangement.

On the other hand the law, as interpreted by the courts, holds that the question of responsibility is not to be settled by the mere existence of insanity, but by the degree or extent of its existence; and in their efforts to establish a legal test of this disease the courts have undertaken to draw an arbitrary line of demarcation between insanity and irresponsibility, which is wholly at variance with nature as interpreted by medical science. I refer to the test, so-called, which is based upon a knowledge of right and wrong and the capacity to judge correctly of the nature and quality of the act committed, this being in substance the decision of the highest appellate court in the State of New York to-day.

In the case of the People against Flanagan (52 N. Y., 467), the court of appeals held that the test of responsibility is the capacity of the defendant to distinguish between right and wrong, at the time of and with respect to the act complained of; and that the law does not recognize a form of insanity in which the capacity of distinguishing right from wrong exists without the power of choosing between them. In other words, that an individual who possesses a knowledge of right and wrong must necessarily possess the power of choosing the right and resisting the wrong with reference to any particular course of action, and that such a man is legally sane and responsible, no matter how far his mind may be unbalanced in other directions. It will be seen that this proposition, or rather this legal dogma, is but a slight step in advance of that formulated by the English judges in 1843, in answer to the questions put to them by the House of Lords in connection with the celebrated case of McNaughton, who was acquitted of the crime of murder on the ground of insanity. In the language of those learned judges: "To establish a defence on the ground of insanity, it must be clearly proved that, at the time of committing the act, the accused was laboring under such a defect of reason, from disease of the mind, as not to know the nature and quality of the act he was doing, or, if he did know it, that he did not know he was doing what was wrong."

From the time this dogma, this judge-made law, was promulgated down to the present day, our courts of criminal jurisdiction, with their traditional regard for precedent, have generally accepted it blindly, and propounded it to juries, in almost identical language, for their guidance in reaching a verdict, notwithstanding the emphatic protest of medical science that such a test is in direct conflict with the known laws of nature, and hence unscientific and false in its application to the mentally unsound.

Mr. Speranza, of the New York bar, in a paper recently presented to the Society of Medical Jurisprudence, referring to the legal test of insanity, said: "Present methods are not scientific, for, although, in theory, the opinions of the highest court are binding on itself and on all lower tribunals, yet by subtle distinction a constant overruling takes place which destroys uniformity. Furthermore, the scientific method is reversed, inasmuch as our courts propound principles and fit the cases to them, so that the question is not whether the principle is right, but whether the case fits the principle. As Judge Holmes has recently said: 'An ideal system of law should draw its postulates and its legislative justification from science. As it now is, we depend upon tradition or vague sentiment, or the fact that we never thought of any other way of doing things, as our only warrant for rules which we can enforce with as much confidence as if they embodied a revealed wisdom.'"

Mr. Speranza went on to draw a comparison between the two sciences of law and medicine. Both should

[1] Read before the American Medico-Psychological Association, at New York, May 24, 1899.

be curative in effect, he said, but as a matter of fact the law is not so at all. This he attributed to the fact that our criminal jurisprudence "looks rather to the past than to the present or future." He continued: "It is conservative almost to the point of stagnation, but the judges who sit in our courts have intrenched themselves behind two ancient principles, which rise up like a Chinese wall against progress and reform. 'Law is the perfection of reason,' they gravely tell us, and 'the king, through his magistrates, can do no wrong'! Grant these premises, and progress becomes an impossibility."

It should be said, however, that prior to the decision rendered by the New York court of appeals in the Flanagan case, already referred to, certain of our judges, imbued with a more progressive spirit, had in their rulings recognized the fact that moral liberty to commit an act is not necessarily accompanied by rational appreciation of the nature and consequence of the act. In other words, that something more than a mere knowledge of right and wrong is requisite to constitute responsibility for crime; that, in order to render an accused person responsible, he must not only know the nature and quality of the act in question, and that it was wrong, but in addition he must possess the power to choose the right and avoid the wrong; that, indeed, as a prerequisite to responsibility for a crime there must exist the ability to avoid committing it. This is in accord with sound medical doctrine. Says Clouston: "Make a man's power of controlling his actions the test. With that view every medical man will agree."

In the case of The People against Stillman, tried in Rochester, N. Y., in 1877, Mr. Justice Dwight in his charge to the jury said: "According to the law of the State which governs you and me in our relations to this case, a man is accountable for the act which he performs, unless his insanity be of such a character as that by reason of a fixed disease of the mind he is deprived either of consciousness of the act, or of the knowledge of the moral and legal quality and character of the act which he committed, or by some disease of his mental nature is deprived of the ordinary power of volition to will that which he knows to be right. That is the legal standard by which you are to be governed. Was his mind so far affected by fixed disease as that he was, at the time he committed the act, deprived either, first, of consciousness that he did the act; or, secondly, was deprived of the power to judge the moral and legal character of the act which he committed, was unable to judge that the act was morally wrong or that it was legally wrong, or that it subjected him to the penalty of the law; or, thirdly, was absolutely deprived by mental disease of the power to will and to do that which he knew to be right?"

The scientific ground here taken by Justice Dwight marks a decided advance in the jurisprudence of insanity, and one which tends to place it in closer harmony with the deductions of modern science. Again, in The People against Kleim, the court held that the accused, in order to render him responsible, "must know that the act was wrong and punishable, and be able to compare and choose between doing it and not doing it."

"This," says Ordronaux, referring to Justice Dwight's charge, "is unquestionably sound doctrine, and it is accordingly most unfortunate that the court of appeals should have entirely overlooked it in their latest decision upon this point as given in Flanagan *vs.* The People. A decision which has summarily swept away the whole progress and reverted us to legal tests of criminal responsibility, which courts in other States are everywhere discarding as unsound."[1] In fact, one needs but a superficial knowledge of mental disease to know that an abstract knowledge of right and wrong is not uncommon in many forms of insanity, other than idiocy or profound dementia.

We have, therefore, on the one hand, the contention of the legal profession, fortified by time and tradition and backed up by judicial decisions, that insanity is a question of law to be determined by the courts according to the form or degree in which it manifests itself; and that legal responsibility in each instance depends upon a knowledge of right and wrong as to the acts committed, at the time said acts were committed; while, on the other hand, the medical profession holds that insanity, in its relation to crime, is always a question of fact to be determined by the aid of medical science, and that whenever its existence can be so determined, the fact should be sufficient to establish the irresponsibility of the accused, regardless of the form or degree in which his disease may manifest itself. In other words, medical science holds that the whole question of responsibility should rest upon the existence or non-existence of mental disease and not upon the presence or absence of a knowledge of right and wrong. This eminently sound doctrine has not only been affirmed by practical alienists in general, but has been attested by formal resolution of the British Association of Medical Officers of Hospitals for the Insane, in the following terms: "*Resolved*, That so much of the legal test of the mental condition of an alleged criminal lunatic as renders him a responsible agent because he knows the difference between right and wrong, is inconsistent with the fact well known to every member of this meeting, that the power of distinguishing between right and wrong exists very frequently among those who are undoubtedly insane, and is often associated with dangerous and uncontrollable delusions."

The serious defect in the legal test of insanity, as established by the court of appeals in the State of New York, is that it undertakes to define positively the degree of mental unsoundness which shall absolve its victim from responsibility for his acts, an undertaking which every practical alienist knows is impossible; that is, it has undertaken to decide what the law of nature shall be, rather than what it is. "Jurists," says Ray, "who have been so anxious to obtain some definition of insanity which shall furnish a rule for the determination of responsibility, should understand that such a wish is chimerical from the very nature of things. Insanity is a disease, and, as is the case with all other diseases, the fact of its existence is never established by a single diagnostic symptom, no particular one of which is present in every case."

The fact that it is impossible to formulate a strictly scientific definition of insanity—that is, a definition which shall embrace every variety of the disease and at the same time exclude certain conditions of mental disturbance or disorder which do not come within our conception of insanity, is in itself the strongest argument against the utility of any legal test of this disease. "And if a fact indefinable in itself, as insanity is conceded to be, is not reducible to a fact in law, then it is unfortunate that the courts should maintain a contest with science and the laws of nature, upon a question of fact which is within the province of science and outside the domain of law."[1] That which in fact is a condition of mental disease cannot in law be a condition of mental health.

In the language of Judge Doe, in the case of The State against Pike, "If the tests of insanity are matters of law, the practice of allowing experts to testify what they are should be discontinued; if they are matters of fact, the judge should no longer testify without being sworn as a witness and showing himself qualified to testify as an expert."

[1] Ordronaux: "Judicial Aspects of Insanity." p. 243.

The French penal code declares that "there can be no crime nor offence if the accused was in a state of madness at the time of the act." The German penal code provides that "an act is not punishable when the person at the time of doing it was in a state of unconsciousness, or of disease of mind, by which a free determination of the will was excluded."

Even in England the rule laid down by her senate of judges in the McNaughton case is no longer the sole guide in determining responsibility for crime, although so great was the weight of authority attached to this decision that it has taken years to overcome its prestige and to supplant it by legislative enactment more in harmony with the greater laws of nature, by which human actions are determined. The English Trial of Lunatics Act now provides that "if it appears to the jury before whom such person is tried that he did the act or made the omission charged, but was insane as aforesaid at the time when he did or made the same, the jury shall return a special verdict to the effect that the accused was guilty of the act or omission charged against him, but was insane as aforesaid at the time when he did the act or made the omission."

The revised Code of Criminal Procedure of the State of New York, section 21, provides that "a person is not excused from criminal liability as an idiot, imbecile, lunatic, or insane person, except upon proof that, at the time of committing the alleged criminal act, he was laboring under such a defect of reason as either (1) not to know the nature and quality of the act he was doing; or (2) not to know that the act was wrong."

It will be observed that the language of the New York statute is almost identical with that used by the English judges in respect to the McNaughton case in 1843, and reiterated by the New York court of appeals in its decision in the Flanagan case, a decision which the trial courts have generally regarded as having the force of law, and which is now embodied in the statute, with the implied approval of the legal profession.

Thus it appears that the lawmakers of the Empire State, following the dictum of her court of appeals, and ignoring the teachings of medical science, have undertaken to determine by statutory enactment what insanity is, and likewise to establish a legal test whereby its presence may be demonstrated. In other words, with a wisdom superior to nature's, they have attempted to define the conditions of responsibility in mental disease by declaring in law what shall be rather than what is, and in so doing have given us a test which is based on a misconception of the true nature of insanity, which has been handed down from generation to generation, and which is so narrow in spirit and so untenable in reason that every experienced alienist must regard it as artificial, arbitrary, and fraught with danger to humanity and the ends of justice. To base the diagnosis of insanity upon a question of the knowledge of right and wrong, that being in effect what this so-called test requires, is directly in conflict with a well-established fact in medical science as well as a serious menace to human rights and individual liberty.

Now, if every form and every stage of mental disease were invariably attended by a loss or suspension of the knowledge of right and wrong, such as usually occurs in extreme types of mania, melancholia, paresis, and dementia—forms or stages of the disease which are usually characterized by mental aberrations so marked as to bring them easily within the ken of the unskilled observer, who could readily recognize them as symptoms which in themselves furnish presumptive evidence of the absence of power to distinguish rationally between right and wrong, no valid objection could be raised to the present legal test of insanity, wrong in principle though it be, for the reason that its practical effect, as applied to the class of cases referred to, would be to establish irresponsibility in substantially every instance, regardless of the nature of the act committed, thus securing the ends of justice. Unfortunately, however, only a small percentage of the insane, who come within the jurisdiction of our criminal courts, belong to the types of insanity above specified, for the reason that, as a rule, this class of insane persons are not homicidal and consequently seldom commit or attempt to commit homicide, or what is technically known as crime against the person; that is to say, they do not belong to the class of insane who are known to be dangerous. As already intimated, practically there is little or no difficulty in determining the question of responsibility in cases of this kind when charged with crime, for the reason that they readily fall within the legal conception and definition of mental disease. It is in a widely different and much more frequently represented form of disease among the so-called criminal insane—insane persons charged with crime—that the application of the legal test of responsibility has proven so unsatisfactory, namely, the "dangerous insane," a large proportion of whom are paranoiacs, or, in other words, victims of systematized delusional insanity, which older writers were wont to call monomania, "reasoning mania," or partial insanity. The obscure and doubtful cases that so frequently puzzle our courts of criminal jurisdiction are drawn almost wholly from the ranks of this now well-understood form of mental disorder. Many of the victims of this form of insanity, contrary to popular belief but as every experienced alienist knows, possess a perfectly clear knowledge of right and wrong in the abstract, and also comprehend, abstractly, the nature and legal consequences of acts similar to those which they have committed. Paranoiacs also are frequently actuated by most powerful motives in the commission of crime, motives similar in character to those which frequently govern sane persons, namely, revenge, vindication of personal honor, self-defence of life or property, etc.; but if we seek for the foundation of these motives we shall find that, unlike the motives of the sane individual, they are not founded on reality, but are the offspring of a diseased or disordered intellect, a psychopathic state, which has deranged the psychical apparatus, so to speak, and left it awry, even though the logical apparatus remains intact. Owing to the obscuration of his mental horizon by this psychopathy, the paranoiac is rendered incapable of completely and harmoniously exercising those physiological functions of the brain which are denominated the intellect, the emotions, and the will. He is prone to premise falsely and to misinterpret morbidly the conduct, the attitude, and the motives of those about him, and while he may, and often does, reason logically, he reasons from wrong premises and in a way that a sane man would not do. "The delusions," says Regis, "are connected, coherent, lifelike, starting from false or misinterpreted data, but eminently logical in their deductions."

It matters little, therefore, whether we admit, with Wernicke and others, that the paranoiac has no defect of intelligence and that his mental weakness is only apparent, not real, or accept the view of Hitzig, that "he does not possess his full mental capital and suffers from a defect of intelligence"; all must agree that the effect of his disease upon his mental capacity is such as to render him incapable of exercising his reason and will power as he would do were he in his normal mental state; and that consequently he should be regarded as neither morally nor legally responsible for his acts. "The true test of irresponsibility," says Forbes Winslow, "should be, not whether the party accused was aware of the criminality of his actions, but whether he has lost all power of control over his actions."

To set up a legal test or standard of insanity which is not in harmony with the teachings of medical science, and at the same time so narrow in scope as to exclude from its benefits the victims of paranoia, who represent such a large proportion of the dangerous insane, simply because they possess a knowledge of right and wrong, is a disgrace to jurisprudence and a travesty upon justice.

The real question of fact for the jury to determine in cases of alleged insanity in criminal trials would seem to be the following:

1. Did the defendant at the time of the alleged crime have sufficient mental capacity to appreciate rationally the nature and consequences of the act he was committing, and, if so, had he sufficient power of will to enable him to choose between doing or not doing it?

2. If he had lost the power of choosing with reference to the particular act, was the loss due to disease and not to "heat of passion," intoxication, or other self-induced temporary mental disturbance?

It must be admitted that a correct solution of these questions, involving as they do, human life and liberty, is of most vital importance; and inasmuch as they relate directly to disease the facts upon which their solution must rest can properly be interpreted for the jury only by competent medical testimony. In other words, substantially the same test should be applied here as is now required by law for the commitment of an individual to a hospital for the insane, namely, an examination of the mental condition of the accused by physicians who are practically familiar with the phenomena of insanity. If this were done it is safe to predict that much of the discrepancy and conflict of opinion in our courts of law respecting the question of responsibility in criminal cases where insanity is alleged would disappear.

85 Madison Avenue, New York.

## THE PRESENT STATUS OF APPENDICITIS: WITH REPORT OF FORTY-FIVE CASES.[1]

By FRANK LeMOYNE HUPP, A.M., M.D.,

ATTENDING SURGEON TO THE CITY HOSPITAL, WHEELING, W. VA.

Several months ago the following questions were sent to a number of the leading surgeons of the United States:

1. What do you recognize as the early and cardinal symptoms of fulminating appendicitis, or what symptoms are the forerunners of a fatal issue in these cases provided there be a delay in surgical interference?

2. Are you in favor of an operation in all cases as soon as a positive diagnosis is made?

3. What percentage of all cases recover from the first attack with spontaneous resolution?

4. What have grape and berry seeds and other extraneous bodies to do with the exciting cause?

The following replies were received:

From Dr. Nicholas Senn, Chicago:

"1. I regard a progressive rise in temperature, increase in pulse rate, obstinate vomiting, and increasing tympanites, as the most ominous symptoms.

"2. I only advise operation during first attack when symptoms arise which point to suppuration or spreading peritonitis. In recurring attacks operation is indicated.

"3. About eighty to eighty-five per cent.

"4. Foreign bodies beside enteroliths are very rare as exciting causes of peritonitis."

From Dr. Charles K. Briddon, New York:

"1. Sudden, severe, constitutional shock, little or no elevation of temperature, and it may be subnormal; rapidly rising pulse, no tumor, but marked muscular resistance.

"2. If the symptoms do not begin to abate at the end of forty-eight hours, I should advise operation. If they subside at the end of that time I should advise the intermuscular operation, two weeks after resolution.

"3. This question could only be answered by a careful search of the records, but my impression is that a large number recover from the first attack.

"4. I can conceive it probable that the fecal concretions so commonly met with in perforative appendicitis may be the occasional cause. In several hundred cases I have found grape seeds only on one or two occasions."

From Dr. Charles McBurney, New York:

"1. In 'fulminating' or very acute cases of appendicitis the early cardinal symptoms are severe, very rapidly increasing pain, early muscular rigidity and distention, frequent vomiting, unusual restlessness, septic appearance, and usually rapidly rising temperature. The patient often, at a very early period, has the look of one suffering from surgical shock.

"2. I am by no means of the opinion that operation should be done in all cases as soon as a positive diagnosis is made. I should as soon think of amputating every hand as soon as a septic wound on the finger was discovered.

"Experience and careful observation will generally enable one to distinguish the cases that will safely end in resolution, after a few days of moderate illness. Such cases should always be allowed to pass through the attack, and operation, a much better one than can be done in the acute stage, should be done within a short time (perhaps two weeks) after the acute signs have disappeared. If one is in doubt as to the safety of delay, operation had better be done early in the acute stage. If it is evident that the attack is severe, operation cannot be done too promptly.

"3. Impossible to answer accurately. Perhaps fifty per cent.

"4. Seeds and other foreign bodies act only as a cause of appendicitis according as they interfere with the proper drainage of the appendix into the cæcum. Strictures and kinks act in the same way by interfering with the drainage.

"Stagnation or undue retention of the contents of the appendix lead to rapid formation of virulent bacteria, infection of the walls of the appendix, ulceration, gangrene, and inflammatory action of the surrounding peritoneum. Interference with the drainage of the appendix is the cause of about all cases of appendicitis."

From Dr. Robert T. Morris, New York:

"1. I do not recognize 'fulminating' appendicitis as variety, only as a degree. The two chief symptoms as forerunners of a fatal issue are commonly a normal or subnormal temperature, and a pulse of high tension averaging more than 120 to the minute.

"2. I am in favor of an operation as soon as a diagnosis can be made, because this in skilled hands avoids the complications due to advancing infection. Certain cases must be excluded; for instance, patients with old alcoholic lesions, or with dilated hearts, or possibly other evident reasons why the compensative dangers from operations or from the disease, call for the exercise of nice judgment.

"3. Without operation about ninety per cent. of cases apparently recover from the first attack, but leave damaged appendices containing concretions, mucous inclusions, and other dangerous relics. About seventy-five per cent. apparently make a final recovery without operation. With operation in my experience

[1] Read before the Medical Society of the State of West Virginia, at Weston, W. Va., May 17, 1899. Read also before the Medical Society of Wheeling and Ohio County.

to date there has been no death rate in cases without abscess, and about five per cent. death rate in abscess cases since 1890, when improvements in technique were perfected.

"4. Seeds and other extraneous bodies have very little place among exciting causes. The real pathology as described in my book [1] seems to have been pretty generally accepted by the profession, in this country and in Europe."

In a recent paper on this subject I find Dr. Hunter McGuire's answers to the questions as follows:

"1. When the attack is sudden and severe, the pain intense, the pulse rapid, temperature high, respiration short and thoracic, abdomen hard and distended, face pinched and anxious, especially if the group of symptoms has been ushered in with a chill, the only hope for life is an operation, and the sooner the better. Such a case is called a fulminating one. It comes on like an explosion, and we are not warranted in waiting an hour to try our medical remedies. In such cases, if along with other symptoms there is shock, perforation will almost certainly be found, and the chances for life are very slight even with an early operation.

"2. I am not in favor of an operation in all cases as soon as a positive diagnosis is made. Too many of them get well and stay well to warrant it, and others can be made to wait during an interval between the attacks.

"3. Fully one-half."

From Dr. Andrew J. McCosh, New York:

"1. The general aspect to an experienced observer of the patient. The appearance impossible to describe of one desperately ill. Pulse of poor quality generally, but not necessarily rapid. Vomiting, tympanites, with absolute constipation.

"2. No.

"4. Foreign bodies are very rarely the exciting cause."

From Dr. Charles A. Powers, Denver:

"1. Perforating appendicitis differs so much in its symptoms that I hardly feel that any train can be considered absolutely pathognomonic. In general we may say that a sudden and severe pain in the right iliac fossa, with rapidly increasing local tenderness and more or less evidence of shock and collapse, points to a perforation into the general peritoneal cavity. I do not think that we can say, early in the course of any case, that this perforation will or will not take place. In certain cases perforation into the free cavity is unaccompanied by any special symptoms, and the evidence of general peritonitis comes on gradually and progressively.

"2. I have not as yet thought it best to operate on all cases as soon as the diagnosis of appendicitis is made, though I am certain that far more errors are made on the side of delay than of that of early interference.

"3. The only contents of the appendix which I have seen have been accumulations of fecal matter and inspissated mucus.

"4. I can form no idea of the percentage which recover from the first attack. Physicians are more apt to see these cases than are surgeons. I am convinced that every case of appendicitis should be seen by the surgeon with the physician at the earliest possible moment."

**Report of Cases.**—During the past three years there have come under my personal attention forty-five cases of appendicitis. Of these forty-five cases there were twenty-two receiving operation, twenty-three not receiving operation. Of the twenty-two cases receiving operation three resulted fatally, and nineteen in recovery. In one of the fatal cases the appendix contained a black pin an inch and a quarter in length, with a glass head; this pin had perforated the tip of the appendix, and had caused a violent diffuse, septic peritonitis; the patient was almost moribund on admission to the hospital, and died in less than an hour after leaving the table. In a second case the patient was moribund on admission, and died on the table before the operation was completed. The third died of septic peritonitis, which was well advanced at the time of admission to the hospital. There were five cases of diffuse septic peritonitis receiving operation, with two deaths and three recoveries. There was therefore an operative mortality of forty per cent. in these cases which hitherto have all been doomed.

Dr. McCosh,[1] reporting nine cases with six deaths, gave a percentage mortality of sixty-six and two-thirds in this same class of cases, three years ago. Of the twenty-three patients not receiving operation five died, and eighteen recovered.

Of the forty-five cases there were thirty-one males and fourteen females.

Case I.—Appendicitis with gangrene and perforation, beginning diffuse septic peritonitis; laparotomy, recovery. J. R. D——, blacksmith, aged twenty-four years, single. He had been constipated all his life. Eight years ago he had his initial attack of appendicitis, diagnosed at that time as typhoid fever. Two months before the onset of his present trouble he had frequent attacks of colicky pains in the abdomen. Sunday, April 18, 1897, he was seized with griping pains in the neighborhood of the umbilicus, which kept up all night. He suffered some through Monday and Tuesday, but continued his work until Wednesday, April 21st. Thursday, April 22d, early in the morning, the pain became localized; there were a chill and some vomiting. The man was seen by his family physician. About midnight, April 22d, he developed a rapid and feeble pulse. The temperature had fallen to subnormal, and the pain in the side had increased suddenly and with violence. He was removed to the City Hospital. At 2 A.M., on admission, the pulse was 146, temperature 105° F., respirations 40 and costal; the face was covered with a clammy sweat, and the abdomen was markedly distended. Operation was performed at 2:30 A.M. under ether narcosis. A four-inch incision was made over the appendix, and when the peritoneal cavity was opened there exuded a stinking, purulent discharge from every part of the wound. The cæcum and part of the ascending colon were bound down firmly by old adhesions, so much so that it was impossible to separate them. The appendix, swollen, gangrenous, and twice perforated, was found hidden away to the outer side and posterior to the cæcum. It was liberated, ligated at its base, and removed. The stump was disinfected by a bichloride tablet. Two hard concretions were found loose in the abscess cavity. After a careful toilet of the peritoneum, gallons of decinormal salt solution having been used, it was found on adjusting some of the folds of the intestine that more pus exuded. Feeling that well-directed drainage could not rid the sensitive peritoneal cavity of this death-deal-

[1] Morris, "Lectures on Appendicitis," chapter iii., p. 16: "Appendicitis is an infective exudative inflammation of the vemriform appendix. Bacteria enter the lymphoid structures and the cellular coats, the stage of exudation begins, and the tissues are compressed by the exudate. In the colon, when infection begins and exudation takes place, there is an abundance of room for swelling. In the narrow appendix there is not room. The lymphoid tissue cannot act as a filter for the bacteria. Compression anæmia is produced, allowing a more rapid toxic destruction of the cells and the toxins produced by the bacteria, and all this occurs before the nuclein can be poured out and the leucocytes and phagocytes can do their work of defence. Proliferative endarteritis begins very early, and this occurs in the small terminal artery, being practically the only arterial supply of the appendix. If the vessel becomes completely obliterated, there is frequent and complete gangrene and rapid destruction of all the parts not supplied by blood."

[1] Presbyterian Hospital Report, vol. ii., p. 141.

ing pus, it was decided that a second incision should be made in the median line. This act was rewarded by the finding of a considerable quantity of purulent exudate, flakes of necrotic material, and some fecal matter well over to the left. The whole abdominal cavity was thoroughly irrigated. The intestines were removed and thoroughly washed on hot towels. The median wound was sutured, but the first wound was left open. Strips of iodoform gauze were carried down to the stump and used also to wall off the gut from the cavity of the abscess. The patient was vigorously stimulated and put to bed. The bowels moved thirty hours after the operation in response to calomel, salines, and high rectal injections.

Fig. 1.—Gangrenous Appendix with a Large Perforation. (Case II.)

Recovery was tedious owing to a high temperature, which ranged, for two weeks following the operation, from 101° to 103° F., due probably to ptomain absorption or to a septic lymphangitis. The patient gained rapidly after the fourth week and was discharged cured the fifth week. He has been perfectly well since and has no ventral hernia.

Case II.—Gangrenous appendicitis with perforation, beginning diffuse septic peritonitis; laparotomy, recovery. W. S——, aged twenty-three years, oil driller. He gave a history of a chill, fever, and abdominal pain three days before he called his physician, who found him with localized pains and a temperature of 104° F. The symptoms all improved under treatment, and nothing untoward developed in the case for five days, when the pain suddenly became unbearable, the pulse increased in frequency, and the temperature was again elevated. April 16, 1897, in the morning he had a pulse of 120, costal breathing, and a temperature of 102° F. I saw him in consultation and advised his removal to the City Hospital. On his arrival he had the abdominal pulse, small, thready, and 136 to the minute, marked distention of the abdomen, and tonic spasms of the abdominal muscles. He bore the appearance of a man in profound shock. Under chloroform narcosis, the abdomen was opened with a four-and-a-half-inch incision. The deep layers were infiltrated and œdematous. When the cavity of the peritoneum was opened, there escaped with a gush a quantity of fetid gas, followed by pus. The intestines were inflamed and were covered with fibrinopurulent and recent catarrhal exudate. A stinking gangrenous abscess cavity was found deep seated in the right iliac fossa. Nature's barrier, the peritoneal lymph, had been poured out abundantly, endeavoring to limit the work of destruction, but the wall had been broken and the damage was done. A gangrenous appendix was found in this cavity, with a large perforation, and was removed. (See Fig. 1.) Gallons of decinormal salt solution were used in cleansing the peritoneal cavity and intestines. A second incision was made, as in the preceding case, and the washing completed. The median incision was sutured and the side wound packed and drained.

In this case five grains of the mild chloride of mercury were given before the patient took ether, and after he had recovered sufficiently from the anæsthetic broken doses of calomel were given hourly. Following this a saline was given together with a high rectal injection; the bowels moved twenty-eight hours after the operation. The side wound healed by granulation; the median wound healed satisfactorily. The patient was discharged on May 14th, cured. He has been well since and is working every day.

Case III.—Appendicitis with gangrene and perforation, beginning septic peritonitis; laparotomy, recovery. Myrtle D——, aged fifteen years, school girl. On May 12, 1897, about midnight, she was seized with violent diarrhœa, vomiting, and cramp pains throughout the abdomen. The symptoms continued until next morning, when she was seen by her physician. The pain had become localized by this time, and the nature of the trouble was evident. May 17th, at eleven o'clock in the evening, I saw her in consultation. Abdominal distention was marked; the pulse was 120, and the breathing was thoracic. I noticed particularly in this case the spasm of the external oblique muscles (described by Dr. Morris), "quick, tremulous flashes of contraction" observed near the costal attachment of these muscles when the region over the appendix was tapped quickly with the finger. Dr. Morris describes it as an extraordinary attempt at protection of the abdominal contents by a set of muscles which are already protecting up to a last degree consistent with the retention of their power. The girl looked ill and her pain was great. I advised her immediate removal to the City Hospital. On admission, on May 17th, at 2:30 A.M., after travelling three miles in a carriage, she was found to be in profound shock. Under ether narcosis, the abdomen was opened by the usual incision. The abscess had ruptured into the general peritoneal cavity. The appendix was swollen, gangrenous, and perforated at its tip, and lying posterior to the cæcum. It was removed and the stump disinfected by the actual cautery. The peritoneal cavity was cleansed after the manner described in the preceding cases. The bowels moved forty-four hours after the operation. As in the first case, the temperature fluctuated between 99° and 103° F. for two weeks following the operation. All this time the wound looked healthy and was granulating. Secondary suture of the wound was made two weeks after operation. The patient was discharged cured on June 30th, and has been perfectly well since.

Case IV.—Acute perforative appendicitis, superficial gangrene of the anterior surface of the cæcum; laparotomy, recovery. J. M——, aged sixty-five years, iron worker; history of constipation; first attack. At four o'clock in the morning of May 17, 1897, he was seen suffering with the most violent abdominal pains, for the most part in the neighborhood of the umbilicus. He had also diarrhœa and vomiting. He presented symptoms of acute indigestion and was treated accordingly. I did not see him the following day, but learned that he had suffered some with colicky pains. The diarrhœa had improved. On May 19th he had well-defined symptoms of acute appendicitis: pain, tenderness, rigidity, vomiting; pulse 96, temperature 102.5° F. He was removed at once to the City Hospital. There were some evidences of prostration on his arrival. He was placed on the table at 11 A.M., and under ether the usual incision was made. Fetid pus escaped from the wound. A large part of the anterior surface of the cæcum was the seat of superficial gangrene. The appendix was swollen, bound down by adhesion, and contained two perforations, one at its tip and the other near the base; the latter extended up through the base of the appendix into the cæcum. This opening admitted with ease the ungual phalanx of the index finger up into the bowel, and through this rotten aperture fecal matter and gas escaped. The appendix was ligated and re-

moved; the stump was inverted, and the cæcal opening was closed by several Lembert sutures.

The bowels moved and flatus passed twenty-two hours after the operation. There was a feculent discharge for eight days. The wound healed kindly, and the patient was discharged June 20th. The scar was perfectly firm.

Case V.—Chronic catarrhal appendicitis, perforation, local abscess; laparotomy, recovery. E. S——, aged twenty years, domestic, came under my observation in September, 1896, suffering with paroxysmal attacks of pain in the epigastrium; often they would appear with intensity, lasting a day or two at a time, requiring morphine. There were several such attacks in a month. The pain was always aggravated by eating. She was anæmic, and had lost flesh and strength, probably due to the starvation diet which she had adopted. Her appetite was poor. Suspecting erosions of the stomach, I made an examination of the stomach's contents, one hour after Ewald's test breakfast. It showed a diminution of free hydrochloric acid; in the washings there was found what seemed to be fragments of the mucosa and some blood-stained mucus. I restricted her diet, gave her peptomanganate of iron, and sprayed the stomach, when fasting, after lavage, with a solution of nitrate of silver, one grain to the ounce, using Einhorn's gastric spray apparatus. She improved, but returned in two months with the same sharp pains in the stomach, radiating toward the umbilicus. The stomach contents were examined, with negative result; on palpation, the stomach was sensitive to pressure, but not specially painful. The woman's suffering continued gradually increasing. She never had had appendicular colic, and was only occasionally constipated.

In this case we note how insidiously the bacteria lurking in the lumen of the appendix were doing their deadly work. While the patient may have had some distinctive gastric disturbance or may have had some dyspeptic symptoms incident to the anæmia, to my mind most of her pain came from the disturbance of the branches of the superior mesenteric plexus, immediately dependent on the constant and mild septic impression from toxins absorbed through the appendix (Morris).

On May 21st the patient was suddenly seized with a sharp pain in the right iliac fossa; her physician was called and gave her relief for the night. On May 22d the pain and tenderness continued, and an examination revealed the presence of a tumor in the right iliac fossa. She was admitted to the City Hospital June 1st, and under ether an extraperitoneal incision was made over the most prominent part of the mass; half a pint of fetid pus escaped. Examination showed the appendix to be hidden away so that to have found it would have necessitated a search which might have endangered the integrity of the limiting adhesions; it was therefore abandoned. The appendix melted away with the discharge. The patient made an uninterrupted recovery, and was discharged cured June 23d. This patient has been seen recently. She has gained twenty-three pounds and is perfectly well.

Case VI.—Acute appendicitis, gangrene, and perforation; laparotomy, recovery. C. N——, aged thirty years, tube worker. On June 28th he was seen by his physician, when he gave a history of an attack of cholera morbus the day previous. He had heavy aching pains in the right iliac fossa radiating into the scrotum and right thigh. On June 29th the pulse was rapid and temperature normal; the countenance presented the appearance of a very sick man. A diagnosis of appendicitis was made.

On admission to the City Hospital he was in moderate shock. Under ether narcosis, laparotomy was performed. The appendix was bound down posterior and external to the cæcum; it was liberated with difficulty, and was found to contain a gangrenous perforation. About three ounces of foul pus was found in the abscess cavity; it was not well walled off from the general peritoneal cavity. In detaching the appendix the omentum presented. It was cleansed and packed off. The wound was irrigated and dressed open. Twelve days after the operation the patient developed a mild phlebitis of the left femoral vein. Fifteen days after the operation he had a chill and pain in the left side, soon followed by bloody expectoration and a mild febrile movement; probably a pulmonary infarction. Aside from this his recovery was uninterrupted, and he was discharged cured May 26th.

Case VII.—Appendicitis, gangrenous perforation, diffuse septic peritonitis following operation; death. L. W——, aged twenty-eight years, mechanic. I saw the patient June 14, 1896. He gave a history of an attack of indigestion with general abdominal pain, which later became localized below McBurney's point. There was difficulty in passing water. On the afternoon of the 14th of June he had a violent attack of pain throughout the abdomen. The usual incision was made under ether and a diffuse septic peritonitis was found. The appendix was gangrenous. It contained two perforations, also a large coprolith. The wound was dressed open. All efforts to combat the shock and to establish drainage through the paralyzed bowels were of no avail, and the patient died two days following the operation. There was no autopsy.

Case VIII.—Appendicitis with local abscess, perforation; recovery. M. M——, aged twenty-three, carpenter. October 4, 1896, he was attacked suddenly with the usual signs. I saw the patient with his physician ten days after the onset. There was a localized tumor with pain and general abdominal tenderness. He was in a septic condition and looked ill. Operation was performed immediately. An oblique incision was made, and a pint of fetid pus was evacuated. The appendix was perforated near its base. The abscess cavity was thoroughly cleansed. Recovery was uninterrupted.

Case IX.—Appendicitis, formation of abscess, perforation; laparotomy, recovery. W. S——, aged twenty-one years, potter. Operation was performed on the tenth day. The appendix was removed through an oblique incision; the wound was dressed open. Recovery was uninterrupted.

Case X.—Appendicitis with perforation, gangrene of the cæcum; establishment of artificial anus; recovery. The usual signs of the disease developed, with pain, rigidity, and local swelling especially marked. The operation was performed on the eighth day of the disease, June 4, 1896. The patient, a little girl aged ten years, was in considerable shock. An incision was made under chloroform narcosis. The general cavity of the peritoneum was carefully walled off with iodoform gauze, and the pus was evacuated, when a necrotic opening was found in the cæcum, near the junction of this viscus with the appendix. There was also a perforation of the appendix. The condition of the patient would not justify any tedious sewing. The open cæcum was sutured to the abdominal peritoneum, and the wound packed. The child rallied from the operation and drifted from under my care. Later the artificial anus was closed, and the patient made a good recovery.

Case XI.—Chronic relapsing appendicitis, suppurating sinuses; laparotomy, removal of the tip of the appendix; recovery. J. H. W——, aged forty years, merchant. I was called in consultation to see a patient who had undergone a radical operation for chronic appendicitis in the Johns Hopkins eighteen months previously. He had a cicatrix nine inches in length in the right iliac region, and about its middle there was

a discharging sinus. The sinus had been kept open with a tube, and was discharging freely, but when the tube was left out for any length of time the wound would fill with pus, causing much pain and discomfort, and a rise of temperature. The patient had lost flesh and strength, was anæmic, and had a cough with expectoration. Under ether the old scar was thoroughly opened through part of its length, and the sinus was followed up deep into the right iliac fossa. Well down behind the cæcum the distal half-inch of the appendix was found and removed. The wound healed by granulation. The man was discharged in three weeks, cured. He gained thirty pounds the first six months after he left the hospital; the cough and expectoration disappeared, and he became sound and well.

Case XIII.—A child, aged four years, from St. Clairsville, Ohio, was seen in the fall of 1899, on the fourth day of a first attack. There was moderate shock on admission to the hospital. An intermuscular incision was made, and the appendix was removed; it contained a fecal concretion in the centre of which were about a dozen raspberry seeds. This finding was verified by Dr. Andrew Wilson under the microscope.

Case XIV.—A boy, aged eight years, with chronic recurring attacks of pain in the right iliac region, with the point of maximum tenderness always over McBurney's point. The pain radiated posteriorly into the lumbar region. The operation was performed in the interval. An intermuscular incision was made and the appendix was removed. It was found to contain a constriction. The general condition greatly improved, but during the first six months the boy had repeated attacks of severe pain in the lumbar region radiating forward into the old scar. The urine contained oxalate of lime crystals. He was treated for renal lithiasis, and for the past year has been perfectly well.

Case XV.—A. E. A——, aged thirty years, tin worker, was admitted to the City Hospital at five o'clock on the evening of the fourth day of his sickness. He was in profound shock and moribund when placed on the table. An incision was made in the usual situation, and the peritoneal cavity was found to be the seat of well-advanced diffuse septic peritonitis. The patient was dead before the appendix was removed. A post-mortem examination was made of the appendix; it contained two concretions and a ragged perforation about its middle.

Cases XVI., XXI., and XXII. were operated on within the last year. In all three cases there were local abscesses; in two the appendix was removed. The wounds were closed by a secondary suture, and the patients made excellent recoveries.

Cases XVII., XIX., and XX. were operations performed in the interval, being cases of chronic recurrent appendicitis. An intermuscular operation was performed, and the wounds healed by primary union.

Case XVIII.—F. W——, aged thirty-three years, priest. The patient was seen in an acute first attack. The operation was performed on the fourth day of the disease. The intestines were carefully walled off with iodoform gauze. The distended gangrenous appendix, the size of a man's index finger, was liberated from the brim of the pelvis where it rested on the right external iliac artery, receiving pulsations from the artery. It was carefully removed. A strip of gauze was carried down to the stump and removed at the end of thirty-six hours. The wound healed kindly. The patient was discharged in less than three weeks after the operation, cured.

The following are cases in which no operation was performed.

Case XXIII.—Acute perforative appendicitis, diffuse septic peritonitis; death. On June 23, 1896, the patient was seized with sharp pain in the right iliac region, which continued for a few hours, and then became general. She was under the care of her family physician, who quieted her pain and kept the bowels well drained. There was little to note in the case until June 28th, when I saw her in consultation. From the history appendicular disturbance was suspected, and a most searching examination was made. Vaginal examination gave negative results. There was tenderness over the entire abdomen, not especially marked over the appendix. The abdomen was pendulous, and very little distended; the finger tips could be carried well down into the iliac fossa. There was absolutely no resistance, and no more pain or tenderness was elicited on the right side than on the left. The pulse was very rapid; the face was anxious. There was no rigidity of the right rectus muscle. The following two or three days, the symptoms were no better defined. The bowels had been opened by rectal injection. The absence of local pain and rigidity and other symptoms referable to the appendix made me hesitate about advising interference at that time. I have since thought that this was a fatal error, and have no hesitation in thus characterizing it, for certainly the history of that first day's pain over the appendix, linked with the abdominal perturbation and overwhelming sepsis, all in rapid succession, ought to to have been sufficient to establish a diagnosis. The woman died on June 30th with ill defined symptoms of septic peritonitis. No autopsy was made.

Case XXIV.—Acute perforative appendicitis, localized collection of pus; improvement without operation; subsequent thrombosis of the mesenteric artery, gangrene of the jejunum; death. W. B——, aged thirty-eight years, engineer. On May 1, 1897, he was taken suddenly ill with abdominal pain and tenderness, rigidity, vomiting, malaise; temperature 103°; pulse accelerated. His family physician, Dr. Taylor, saw him the following day, when he presented the symptoms above mentioned, and a diagnosis of appendicitis was made. The symptoms subsided under treatment, and he was discharged very much improved, May 6th. On May 14th he felt so well that he reported to the railroad authorities that he would be able to resume work in a few days. On the night of the 14th he was seized with an attack of vomiting, which was thought to have been due to some indiscretion in eating. He was given gastric sedatives; the stomach was irrigated, and counter-irritation was used, but the vomiting continued. Morphine relieved only temporarily. He vomited until he died, May 20th.

Autopsy: There were numerous adhesions in the right iliac fossa. The appendix was five and a half inches long and was coiled upon itself. There was a perforation about its middle, and when the adhesions were broken at this point there escaped about a thimbleful of pus. The bowel at the ileo-cæcal junction was healthy. A portion of the jejunum, about four feet in length, in marked contrast to the rest of the bowel, was of an intense purple-black color. A fibrinous clot had formed at the bifurcation of the mesenteric artery, which supplied this part of the bowel. The condition of gangrene extended into the mesentery, which formed a thick black, apoplectic cake. Upon opening the intestine it was found to contain a quantity of dark-red grumous fluid. The wall was thickened to three times its usual dimension. It is interesting to note that there were but three marked symptoms: a deep, heavy soreness in the bowels, an uncontrollable vomiting, and a condition of constant unrest. There was an absence of blood in the stools, said to be one of the most notable symptoms of gangrene of the bowels.

Case XXV.—Perityphlitic abscess, followed by abscess of the liver; perforation into the bronchial tube, pyæmia; death. W. C——, aged thirty years, farmer. The patient had been treated by his physician in West Alexander, Pa., for about one week, for a swelling in the right iliac fossa with acute symptoms. I saw him in consultation about the twelfth day of his disease, when he presented every evidence of an abscess in the right iliac region. I advised immediate operation, but the proposition was rejected. During the following week he was visited by two other surgeons, and their advice of surgical interference was likewise not heeded. I learned afterward that the abscess travelled upward, and evidently involved the liver, finally breaking into the bronchial tube. Death was due to pyæmia and exhaustion. There was no autopsy.

Case XXVI.—Appendicitis with perforation, local abscess, and rupture into the bowel; recovery. The onset was sudden; the patient was ill three days before he was seen by his physician; he then had the usual symptoms. I saw him on the eighth day of his disease, and while I was preparing for the operation the abscess broke and discharged by the rectum. Recovery occurred without incident.

Case XXXVI.—A woman, aged forty-five years; diffuse septic peritonitis on admission, and moribund. The appendix was removed after death and was found to measure eight inches in length, and contained two perforations (see Fig. 2).

Cases XXVII., XXVIII., XXXI., XXXII., XXXIII., XXXIV., XXXV., XXXVIII., XL., XLI., XLII., XLIII., and XLV. were chronic, but mild in character without any systemic disturbance, or were acute catarrhal cases without any tumor to be felt save some slight resistance, or any other threatening indications. These came under my observation at the time when their last attacks seemed to be subsiding, and were proper cases for rest in bed and diet. All such patients, however, are always placed on their guard and are informed that an operation may some day be necessary. With Dr. Andrew J. McCosh, I can truthfully say that I have never felt that all cases of appendicitis should be subjected to operation. A certain number of patients recover without surgical interference, and recover permanently. It is to me one of the most difficult problems in the whole realm of surgery, one of the most vital importance, to decide the most favorable moment for operation. Certainly the closest observation and a considerable experience are needed. The general aspect of the patient is more important to my mind than any group of so-called cardinal symptoms.

Case XXIX. exhibits the difficulties which often present themselves when we attempt to differentiate between an abscess arising from the right Fallopian tube and one of appendicular origin. There were two distinct masses to be made out, and a thoroughly septic condition obtained. Operation was refused. Nature made a way by evacuating the pericæcal abscess into the rectum, and two days later there was a discharge by vagina of a sausage-shaped tumor which lay to the right of the uterus.

Case XXX. was post-typhoid; the abscess discharged by rectum, and recovery was complete.

Case XXXVII. I saw at Lake George, N. Y., while on my summer vacation in 1896. A girl, aged eighteen years, in a third attack, presented symptoms of acute catarrhal appendicitis. Operation in the interval was advised, but all overtures in this direction were rejected. This young lady died during her fourth attack of septic peritonitis the following winter.

After a very careful study of the literature of this subject, and an experience based upon the recent personal analysis and care of upward of fifty cases, I wish to give as my opinion that there is a period in the course of every case of appendicitis at which life may be saved by operation. In the words of Dr. Hermann Mynter: "The prognosis depends solely upon this point of time. We ought immediately to operate in every case which commences with acute severe pain, vomiting, rigidity, fever, and does not recede inside of twenty-four hours, as we cannot know positively the condition of the appendix, or whether there is a commencing gangrene or even perforation present."

Fig. 2.—Appendix Eight Inches Long with Two Perforations. (Case XXXVI.)

We must not be deceived by a lull in the acute signs after twenty-four to forty-eight hours, as may be seen from Case XXXIX. as follows:

The patient was a man aged forty-four years, weighing over two hundred and fifty pounds, with a fatty heart. The pain was so severe on Friday and Saturday that morphine had to be used by his physicians in large quantity; the pain was localized, and the man had a temperature of 102° F. I travelled forty miles into the State of Ohio, and saw him on Monday, which was the fourth day of his second attack. His pulse was 80, temperature 99.5° F.; there was neither pain nor rigidity; very slight tenderness was present all over the abdomen, without any reference to the region of the appendix; there was no nausea or vomiting at the time of my visit; the expression was good; the patient was sitting half up in bed, as though nothing was wrong. He had received no morphine for twenty-four hours that might have masked the symptoms, and everything pointed toward resolution. His three physicians agreed with me that it was a case for conservatism and watchfulness. I returned to Wheeling the next morning, and received a message that evening that the man had suffered through the forenoon with lancinating pain all through the abdomen, and that he seemed to be in a condition of profound prostration. I returned by a special train, arriving at midnight, in time to hear the dying words of a victim of delay. The autopsy made that night revealed a diffuse septic peritonitis and a gangrenous perforation of the appendix. There was no visible effort on the part of nature to wall off the death trap. Medical treatment in such cases is certainly of no avail.

In conclusion I would say: Put, if you will, into the one scale the lives that will be saved, and the amount of suffering that will be obviated; into the other scale let there be put what is considered to be a fair estimate of the risks entailed by up-to-date surgical treatment, and I would contend (with Dr. Hawkins of

London) that the balance can be read only in one way.

There has developed in the last few years a very interesting question regarding the attitude of the insurance companies toward persons who have had appendicitis. Through the kindness of my friend, Dr. John L. Dickey, of Wheeling, I am able to give to the profession an up-to-date answer to this question.

I herewith submit letters from several of the leading insurance companies of this country, received by Dr. Dickey in answer to inquiries made in this direction. These life-insurance men look at this and all other subjects in the very practical way of "Will it shorten the applicant's life? If so, how much?" It is very obvious that their evidence is altogether on the side of operation.

From the Equitable Life Assurance Company of New York:

"In reply to your favor of April 3d, in regard to men having had appendicitis, I beg to state that if the appendix has been removed, we are willing to accept a case as soon as the wound has sufficiently healed to demonstrate whether there will be any hernia or not. Of course, if there is a hernia, we must have a statement that the man wears a bandage or truss, sufficient to control the bowel. Where men have had appendicitis and have not been operated upon, we do not like to accept until they have gone quite a number of years without a recurrence. As you very well know, this disease is apt to return, and the recurrence is apt to be more severe than the original attack, so that we always make them wait until a number of years have elapsed without any recurrence.

(Signed) "Edward W. Lambert, M.D.,
"*Medical Director.*"

From the New York Life Insurance Company:

"Regarding the subject of appendicitis upon which you have addressed me, permit me to state in reply, that the New York Life is prepared to accept risks upon this class of cases; and should any applicant be sent to you for examination, kindly examine him, and on your examination blank submit full details of his illness. Of course, in a case where an operation has been performed, we can offer a much better policy, in fact our Ordinary Life Policy, and in other cases we issue a policy with a lien attached, which lien is lifted from the policy after the lapse of five or six years. This inquiry is along the same line which I addressed you a communication some time since, regarding the examination of sub-standard risks. Since the new departure which this company has assumed regarding the acceptance of under-average business, we have been obliged to modify our instructions to medical examiners to a considerable extent, and I am at present engaged in revising our instructions, and hope before long to be in a position to mail you full directions. Until then, when any case presents itself to you for examination, unless he is at the time suffering from some acute ailment, examine him and submit the papers with detailed account of the impairment. What we require is a pen-picture of the applicant as he stands before you.

"S. Oakley Vander Poel, M.D.,
"*Medical Director.*"

From the John Hancock Mutual Life Insurance Company of Boston:

"In reply to yours of the 3d inst., in regard to the insurableness of those who have had an attack of appendicitis, permit me to say that my rule and that of most companies is as follows:

"An applicant who has had recurrent attacks of appendicitis is not insurable. If he has had one attack and the appendix has not been removed, two years at least should go by before he can be considered. If the appendix has been removed by operation, it is in most cases proper to allow a year to elapse before considering the applicant for insurance. Under these circumstances, before a policy can be issued, it is necessary to know whether there is any hernia as a result of the operation, and whether the parts are soft and pliable, and that there have been no abnormal symptoms since the operation was performed.

"Frank Wells, M.D.,
"*Medical Director.*"

From the National Life Insurance Company, Montpelier, Vermont:

"Replying to your inquiry of the 3d inst., I will say that our rules for the disposal of cases in which there is a history of appendicitis are as follows:

"First: Those cases in which recovery occurs without operation, are postponed three to five years from date of last attack. This group is the most difficult of all to select properly, and a certificate from the attending physician is usually required.

"Second: Recovery with drainage of abscess through the bowel; postponed five years.

"Third Successful removal of the appendix, accepted after one year from date of the operation, if no symptoms indicating pernicious adhesion have been manifested. Certificate from attending physician required.

"Fourth: Operation for opening of abscess without the removal of the appendix; postponed from three to five years. "A. B. Bisbee, M.D.,
"*Medical Director.*"

From the Provident Savings Life Assurance Company, New York:

"There is but one rule in this society, viz.: rejection unless the applicant has been operated upon and the appendix successfully removed. No cases are taken where there has been no operation, the matter of time not entering into the question as a factor.

"F. S. Grant, M.D.,
"A. L. Vandewater, M.D.,
"*Medical Directors.*"

## ON THE PREVENTION OF TUBERCULOSIS.

By CARL STRUEH, M.D.,

CHICAGO, ILL.

When a disease is as destructive in its character as is tuberculosis, it is a matter of course that we do everything in our power to prevent the spread of it. We must, however, take care in doing so not to go too far out of our way. We should not waste time and labor to arrive at the desired end by "roundabout" roads. Otherwise we will find the truth only after having passed through all possible errors and disappointments. One of our preventive efforts of to-day, which in the near future will be found of no avail, is the slaughtering of tuberculous cows. Because a number of persons who drank the milk of cows infected with tuberculosis became tuberculous, the milk is at once made responsible for the infection. It is not sufficiently considered that a great many people drank of the same milk without having become infected, and we readily explain this fact by saying these people were not disposed to the infection. We satisfy ourselves with this most superficial explanation without considering to any extent that it is just this disposition which we must regard as the key to the whole question of contagion. There can be no contagion without disposition, *i.e.*, without abnormal cellular conditions. Our efforts, therefore, should be directed toward influencing the cellular life by hygienic means, instead of our making it a principal aim to avoid or destroy the bacilli.

Even if we would admit the bacillus to be the exclusive cause of infection, it would not be in our power to avert it, because we are exposed to it under any and all circumstances. It is very much to be deplored that we still have an entirely erroneous conception of the condition we call disease and of the mission of the bacilli. We still look upon disease as a self-created, self-existing condition, a punishment from heaven against which we are powerless, while in reality it is the necessary consequence of our irrational mode of living, which we are addicted to partly as voluntary slaves of our desires and passions, partly forced to through our social conditions, and which our grandfathers and grandmothers were accustomed to practise voluntarily or involuntarily. Disease is the necessary consequence of our violation of the conditions of health. We know that the existence of every plant and every animal is dependent on certain conditions. If these are not fulfilled, certain consequences must follow. I know that every flower needs water, air, light, and sunshine, and if I deny it these conditions of existence, a certain result must follow the deficient care; it will wither and go to ruin. I know that I must give my gold fish fresh water at times, if they are to remain healthy and live, and if I do not attend to their requirements, if I leave them in the stale water too long, they will soon show visible suffering and die. Similarly it is with man. He must comply with certain conditions of health. His diet must be a proper one, his daily work must be suitable to his constitution, his rest and sleep must be in conformity with his mental and physical labors, etc. A neglect of duty which nature imposes upon us for a healthy life must have consequences similar to those which we perceive in an animal that is not kept as its nature requires. Indeed our entire mode of living is the reverse of nature's demands.

We have long sought the source of internal disease, and were greatly relieved when we discovered the wicked bacilli. These must now answer for everything, although they are as useful in the household of nature as are vermin and every other living thing that exists. "What is in nature, is filled with sense" (Hegel). We have only to think of the way we live, which in every respect is contrary to the laws of nature, and to consider the daily maltreatment of our digestive organs and nervous system, to see evidences right and left for the cause of illness. The bacilli do not take foothold in any organism until we have caused in it an abnormal condition of the cellular life through our irrational living. The bacilli stand on a level with the vermin. There are plenty of people who believe the latter are there for no purpose, while their existence teaches us a very important lesson, the lesson of cleanliness. If we do not follow this lesson, consequences must follow. If we suffer the dirt in our houses to accumulate, if we reject the sunlight, if we keep doors and windows closed to the oxygen of the air, vermin will make their appearance, and as long as filth is allowed to remain, the vermin will remain too. We cannot expect, of course, that nature should present us with these creatures in a pleasing form, otherwise we might enjoy them as pets, but they are made obnoxious and troublesome to us in one way or another, for thereby we are forced to rid ourselves of them, which we can do only by observing cleanliness. Most people are forced to cleanliness only through their fear of vermin. If no vermin existed, a large percentage of the human race would perish in their own filth. A similar mission as that of the vermin is the mission of the bacilli. As the former remind us of and force us to cleanliness, so do the bacilli remind us to live according to the laws of nature. We will understand this better when once we shall have arrived at the conviction that all internal diseases are but the natural consequences of our absurd mode of life, and that our chase after the bacilli, which can settle only upon already diseased cells and never upon healthy ones, is in vain. "Pathology is physiology." The cells of our organisms must be in an abnormal condition, unfit for their natural functions, before they can become "infected," *i.e.*, before bacilli can settle on them. The experiments on animals by no means contradict this assertion, for we always experiment on animals which also live under conditions contrary to nature. We do not experiment on rabbits roaming over grassy greens and living on cabbage in the fields, but on those that are kept in dark stables or narrow cages in which they cannot live and move about as was nature's intention they should. By our denial of their natural requirements we weaken their vitality, their resisting-power, and cause them to be in an abnormal state of health, although we may not be able to discern this fact with our ordinary senses. The line where health ends and disease begins is completely hidden from our perception. If the harmonious activity of our organism is disturbed in such a manner that parts of the latter are unable to perform their functions, they will form a dead substance that is to be dissolved and destroyed by the bacilli. Where there is no such substance, no bacillus will find the conditions for its existence. If our vitality succeeds in removing the disturbance which caused the presence of dead substance, *i.e.*, dead cells, there will be no further necessity for the presence of bacilli after they have accomplished their purpose, the dissolution of the dead substance into its constituent particles. So the bacilli are not there to cause but to cure disease. They retire because there is nothing more for them to do. But it should not be understood that their retirement made us well; on the contrary, they retire because we became well. If on the other hand our vitality is not successful in removing the disturbance, the formation of dead matter will go on, and the presence of bacilli continue, and death must finally follow because we are unfit for further existence, because, according to the law of nature, only the fit shall survive and the unfit be exterminated. We will, therefore, be compelled to centre all our thoughts and actions upon making the general and individual conditions that surround us as conformant to health as is possible, for only by doing so can we keep in health and make ourselves immune against all influences producing disease. As we can cure consumption only by placing the patient under conditions which are calculated to strengthen his powers of resistance, so we can prevent consumption only by the same means. Only by perfect public and personal hygiene will we be enabled to prevent the spread of tuberculosis, but never by such one-sided means as are characterizing all our present efforts. The slaughtering of tuberculous animals, too, is a one-sided measure, by which we shall achieve little that is material. First of all we ought to consider to what cause the tuberculosis of the affected cows can be ascribed. Will the slaughtering of the animals remove this cause, or will not the following generation of cattle be exposed to the same influences? And if we must affirm the latter question, what purpose is there in destroying those few animals? The question is not simply of one animal being "infected" by another. Before the tuberculous "infection" can take place the animal must be susceptible to contagion, *i.e.*, the cells of its organism must already be disturbed, be in a diseased condition. And, therefore, we should above all try to find the cause of this disturbance, which doubtlessly arises from any abnormal conditions under which these cows are kept. And we should do the same thing in regard to man. We cannot drive tuberculosis out of the world without going to the trouble of giving up our ac-

customed unnatural mode of living. If we could, it would be an easy task indeed, but there is not and never will be such an easy way to prevent the spread of tuberculosis. We can do so effectively only by living as nature demands. Herein lies the whole secret of the prevention of tuberculosis. It is true that this will demand many a sacrifice of us, the denial of many an enjoyment and pleasure that have come to us through civilization; but we must make these sacrifices, lay upon ourselves those denials, if we desire to reach a happy end and help to bring about the time when the world will be populated with healthy human beings again, when so frightfully large a percentage of the race will no longer fall victims to tuberculosis as is the case at present. We must learn to live according to the laws of nature, and we must bring up our children in conformity with them. Only in this wise shall we free after-generations not only from tuberculosis, but from most chronic diseases which we have created ourselves. All attempts to prevent the spread of consumption in any other way, however well meant, will prove futile. Let the means employed appear ever so scientific and plausible, we shall at last come to the conclusion that we attempted the impossible. The late congress for the prevention of tuberculosis seem to have arrived at the same conviction. Not from the use of tuberculin or from chemicals, not from one-sided ineffective measures can we expect material success in the prevention and cure of tuberculosis, but only and alone from a strict observance of the ever true and inexorable laws of nature.

### REMOVAL OF EXOSTOSES OF THE EXTERNAL AUDITORY CANAL WITH A HOOK.

By GEORGE B. McAULIFFE, M.D.,

NEW YORK CITY.

During the last six months I have removed from the external auditory canal of three patients, by means of a hook, exostoses which were the primary cause of deafness in two of the cases and the secondary cause in the third instance, in which the disability was hastened by the impaction of cerumen. The exostoses were in each case in the right ear and took origin from the posterior or postero-superior wall, by a base which was small compared to the size of the growth; yet, before removal, the tumors gave no evidence of pedunculation. One, in fact, was thought to be a hyperostosis. Pathologically they belonged to the polypoid form of exostoses, more often seen than either the broad-based, irregular, dense hyperostoses associated with an old otorrhœa, or the pale, rounded, eburnated, slow-growing neoplasms caused by the constitutional dyscrasiæ. No history could be elicited which would throw light on the cause or period of development. The present attack of deafness was the first experienced. From the fact of the situation of the growths in the right ear, it might be conjectured that the cause lay in the existence of a localized hyperæmia, set up by the habit of picking the ears—a habit which would obviously endanger the right more than the left ear and the posterior more than the anterior wall.

Heredity and the influence of brachycephalus, in the causation of local hyperæmia in the formative stage of the external auditory canal, would not enter into the consideration of unilateral growths.

The removal of exostoses has generally been accomplished by means of the chisel, gouge, trephine, or drill, or by modifications of these instruments, designed to protect the deeper structures. The auricle is occasionally disengaged from its bony attachment, to facilitate the operation. In none of the numerous cases reported have I seen mention made of the use of such a simple instrument as a hook, in the removal of these growths.

It so happened that these cases came under observation when either no opportunity existed for anæsthesia or time was not available for extensive surgical interference.

One of the heads of Cook's Tours came, on the eve of his departure for Yellowstone Park, and complained of deafness. The lumen of the external auditory canal was filled by a spheroidal exostosis, the surface of which was coated with cerumen. Cleansing the growth did not improve the audition. The probe revealed more space in the anterior superior portion of the canal than elsewhere. Unable to encircle it, I passed a small hook along the growth, in order, if practicable, to make a channel for audition, until there was an opportunity to have the growth removed. The exostosis was then found to have a slight mobility. Securing a firm hold on the posterior surface by the hook, I made traction, which was completed by the sudden jerking away of the patient. The growth was broken off from its basal attachment and was found to be the size of a small marble. The canal beyond and the drum were found to be perfectly normal, and audition was perfect.

A second patient was placed on the table by a surgeon who proposed to lay forward the auricle, and by means of chisel and mallet to disengage the growth. As soon as the man began to take ether he had a violent epileptic fit. The operation was abandoned for that day. A few days after he came to the clinic, and, remembering my former experience with the hook, I repeated the procedure on him and succeeded, after a few attempts, in evulsing the growth.

A third case presented itself a few months later, and, although the exostosis was deeply seated and had the appearance of a hyperostosis in the usual situation, I tried the hook, and was pleased to find that, after a few attempts made to secure a hold, the entire growth came away.

In these cases, there was scarcely any pain experienced in the evulsion. The inflammatory reaction was slight, and under simple surgical treatment the canal healed readily.

### NEPHRORRHAPHY AND STRIPPING OF THE APPENDIX THROUGH A LUMBAR INCISION, FOR RIGHT FLOATING KIDNEY AND PAINFUL APPENDIX.

By J. COPLIN STINSON, M.D.,

SAN FRANCISCO, CAL.

The following case of right floating kidney and painful appendix, operated upon March 26, 1897, is reported as it illustrates operations on the kidney and appendix performed at the same time through the lumbar nephrorrhaphy incision.

Mrs. M——, aged twenty-two years, began to menstruate at the age of eighteen. She had no pain, but was irregular as to time and duration. She would flow twice or thrice a month. She was married in 1896, and two months afterward commenced to suffer with painful menstruation. She was fond of out-door and physical exercise. In 1895 she fell from a horse to the ground, striking on her back; she complained of pains in the right loin, and a week later began to have pains also in the right side of the abdomen. Later nearly every evening, after being on her feet all day, she had severe pains in the right loin and the right side of the abdomen, dizziness, and vomiting. With the recumbent position and the application of

heat to the abdomen she was relieved of most of the pain. She took medicine several times a day right along, and after her marriage was treated in addition with electricity and vaginal tampons with little or no relief.

I was called to see her in March, 1897. Her general health was below par. She was very nervous, menstruation was painful, appetite and digestion were poor, bowels constipated, no evacuation for four days; pulse 98, temperature 99° F. in the morning, 100.5 F. in the evening. She suffered from pain in the right loin and right side of the abdomen, and had some vaginal discharge. The uterus was markedly anteflexed, the appendages were normal; the right side of the abdomen was painful and tender, with marked tenderness over the region of the appendix vermiformis. I ordered hot douches of potassium permanganate, 1 : 2,000, hot applications to the abdomen, codeine sufficient to relieve pain, free saline catharsis, and rectal injections of soapsuds, containing also castor oil and Rochelle salts. After the bowels had moved freely I again examined the abdomen, this time with the patient sitting in a chair, her feet resting on a small box, with the abdominal muscles relaxed. I detected a right movable kidney, which with pressure could be replaced and with a blow on the loin again displaced. The pain and tenderness over the appendix persisted after the kidney was replaced in the lumbar region. Her temperature and pulse became normal in a few days.

On March 26, 1897, I performed operation with the kind assistance of Dr. G. Gross. Chloroform was administered by Dr. N. Selling. A lumbar incision was made along the outer edge of the erector spinæ from the twelfth rib to near the iliac crest; the structures of the loin were divided, and the fatty capsule picked up and torn vertically upward and downward. The kidney was pushed toward the incision by pressure of Dr. Gross' fist on the right side of the abdomen; it was inspected, palpated, and the tunica propria freely exposed by trimming away the fatty capsule. The peritoneum was opened on the outer side of the kidney and the colon located. The appendix, cæcum, etc., were drawn up into the wound. The appendix was examined by immediate palpation, and contained a small semisolid mass, but did not show other evidences of infection or inflammation. The contents of the appendix were pushed into the cæcum by stripping the canal with the fingers from the distal or blind end to the proximal or open end of the appendix (the appendico-cæcal junction). The semisolid material was in all probability a concretion and the cause of the pain and tenderness over the appendix, as these symptoms did not reappear afterward. The appendix was not extirpated, as it otherwise appeared normal. The cæcum, appendix, etc., were replaced in their normal positions, the cut edges of the peritoneum closed, and the kidney was fastened to the lumbar fascia by four interrupted stitches of chromicized kangaroo tendon. The cut edges of the muscular layers were sutured with tendon and the skin was closed with fine silk without damage (Dr. J. C. Stinson, on another method of fixation of the kidney, in the MEDICAL RECORD, April 17, 1897). The patient recovered, the wound healing by primary union. All the dressings were removed April 13, 1897.

About two months later chloroform was administered by Dr. Gross while I dilated the cervix and curetted, irrigated, and drained the uterus to relieve her of the anteflexion and painful menstruation. She again consulted me in July, 1898, suffering for several months with a fissure of the anus which extended up into the rectum for over an inch. The sphincter was stretched, the base of the ulcer incised, and the overhanging edges of mucous membrane, etc., were trimmed away. The recto-anal wound soon healed.

My attention was called to this case by reading some articles very recently written by Dr. G. M. Edebohls. In the *New York Post-Graduate Journal*, February, 1899, in an article on "Chronic Appendicitis, the Chief Symptom and Most Important Complication of Movable Right Kidney," Dr. Edebohls stated that "the lumbar operation for chronic appendicitis, or rather the simultaneous fixation of a movable right kidney and removal of a chronically diseased appendix through the lumbar nephropexy incision, was conceived and first put into execution by the writer,"[1] to meet just the class of cases we have been discussing this evening. His experience with the operation dates from June, 1898, and is rather limited, embracing only eight cases.

I call attention to this, my earliest kidney and appendix case operated upon at the same time through the lumbar kidney incision, as it dates from March, 1897. From an operative standpoint it is very similar to Dr. Edebohls' earliest case operated upon in June, 1898, with the exception that in my case the appendix was palpated and stripped of its contents, while in Dr. Edebohls' the appendix was excised.

326 KEARNY STREET

## AN IMPROVISED VACCINE EXPELLER.

BY ARTHUR IRVING BOYER, M.D.,
ACTING ASSISTANT SURGEON, UNITED STATES ARMY.

IN the London *Lancet* for February 11, 1899, notice is given of a "vaccine expeller" invented by J. H. Montague, which "is intended for the expulsion of lymph from capillary tubes without resorting to the time-honored method of blowing it out with the breath." Any one who has gone through this "blowing it out" process will appreciate any mechanical apparatus which will relieve one of the necessity of becoming a compressed-air tank.

It was while engaged in work of this character that the thought occurred to me to use an ordinary hand bicycle pump, attaching the very small rubber tube (such as comes with the vaccine) to the flexible end of the pump, the joint being made air-tight by a wrapping of adhesive plaster. The ends of the capillary tube being broken, the pump is attached to one end, and one stroke of the piston accomplishes the desired result. It has advantages over the "vaccine expeller" spoken of, in that it is simple, certain of action, easily obtainable, inexpensive, and is not affected by climate or disuse, as are goods made wholly of rubber.

COAMO, PORTO RICO.

## A TYPICAL CASE OF VACCINELLA.

BY W. E. FOWLER, M.D.,
PHYSICIAN TO THE HUNTSVILLE, TEXAS, PENITENTIARY.

SINCE the day on which the world was startled with wonder and electrified with gratitude by reason of the announcement of the immortal Jenner that he had discovered and reduced to practical utility an effective preventive of smallpox, there have not been found any very large divisions of the globe where the people were—or are—in accord on the subject of its application. Indeed, it is the rule, and not the exception, to find a large number of people opposing the practice of vaccination whenever smallpox makes its appearance; nor does this opposition emanate alone from the ignorant masses—by no means. On the contrary, we find men and women of the first order of intellect earnestly and conscientiously opposing this easy means of escape from one of the most fearful

[1] G. W. Edebohls: "Wanderniere und Appendicitis, deren häufige Koexistenz und deren simultane Operation mittels Lumbalschnitt." Centralbl. f. Gyn., 1898, xxii., 1084.

pests known to the mortuary reports of the world. This is a fact hard to account for; but I am inclined

FIG. 1.

to believe that the opposition has its source in that peculiar freak of human nature (manifested in a goodly number of people) which stimulates a certain amount of antagonism to all public authority. So, therefore, whenever a police decree goes forth ordering the vaccination of the inhabitants, straightway is heard a doleful howl regarding oppression and persecution. But this is by no means all that can be said with respect to this phase of the subject; for very many intelligent people—willing at all times to submit to whatever measures of authority that may be devised, having for their object the preservation of the public health—are found strongly averse to being vaccinated. And we must admit that some of the arguments of these people are very ingenious, if not logical in presentation.

I am of the opinion that much of this opposition (aside from the above suggestion) arises from the occasional well-marked and typical cases of vaccinella, which, as all medical men know, very much resemble true smallpox—even subjectively as well as objectively. Of course I had heard of these sequelæ of vaccination, from brief references in the text books and clinical notes appearing in the journals; but, until recently, it had never been my good fortune to see a well-defined case. Other physicians, with larger fields of labor and greater variety of work—may think my case a very simple one; but, as it has interested me and others who have seen it, I have thought it might be of interest also to the readers of the MEDICAL RECORD.

To illustrate the case more thoroughly, I have had the subject photographed, as shown in Figs. 1 and 2, front and back views respectively. The subject is a negro, aged thirty years, a laborer. He came to the hospital March 19, 1899, suffering with tertiary syphilis, but without any well-marked centres of attack, such as gumma, specific phagedæna, etc.

On the day of his admission I noticed a well-developed vaccinal ulcer at the insertion of the deltoid muscle of the left arm; and, upon inquiry, I found that he had been vaccinated two weeks previously. A few days later there appeared a number of blebs or vesicles about the primary sore. Next day numerous papulæ were seen about the face and neck, and from these points they rapidly spread over the body; but the eruption seemed to have choice of parts, as the illustrations will show—having a tendency to skip certain portions, while attacking in force at other points. The vesicles were transformed into pitted pustules, following, in this respect, the phenomena seen in cases of genuine small-pox; and the peculiar odor was identical with that of the true disease. In fact, the phenomena throughout have been those of smallpox, with the single exception of the absence of pyrexia, there being absolutely no elevation of temperature, save on two occasions, and then it did not exceed 100° F.

He was photographed April 24th, a few days after the appearance of active desquamation. I deem it unnecessary to give the treatment, as it was merely of a calmative and antiseptic nature; suffice it to say that the patient is measurably well, and that there appear to be no other symptoms out of the ordinary. It might be well to note that the specific treatment has not been abated.

Now, it is a very well-known fact that one of the direct effects of vaccinal lymph in the system is to aggravate any cutaneous diseases present; this I personally know to be true, as it is clearly demonstrated in the cases of patients now under treatment here; and as many of the most marked manifestations of syphilis are of a cutaneous character, I have associated the progress of my case with this disease.

HUNTSVILLE, TEXAS.

## A PIPE-STEM IN UTERO.

By WILLIAM J. GREANELLÉ, M.D.,
NEW YORK.

S. J——, female, colored, a cook by occupation, was sent to me by her mistress for relief from "irregular menstruation." She stated that she was twenty-seven years of age, a widow, and that her husband had been dead two years. She had, so she said, suffered from irregular menstruation with some colicky pains for five or six months, and that she had been under treatment during this time at varying intervals, but without relief. Menstruation (she said) had appeared at intervals of two and three weeks since December last, the last flow having appeared a week prior to her first visit to me. When asked if she had at all thought that there might have been some "special cause" for her troubles (pregnancy) she said, "My husband has been dead two years."

On bimanual examination I found the uterus somewhat larger than a Bartlett pear, and, most astonishing, a hard body presenting from the cervix. With some difficulty I succeeded in extracting a semi-cylindrical affair to which was attached a small loop of string. Somewhat confounded at first, my patient finally took refuge in the statement that she thought "the other doctor had put it there" (six weeks before), but on urging her I succeeded in getting her to admit that she "might have been pregnant, but did not know it." She claimed never to have seen the foreign body before.

When this foreign body was washed and dried, I came to the conclusion that it was a half of a celluloid pipe-stem. Evidently an old pipe-stem had been soaked in water until it had straightened out and split longitudinally. Along the centre of the flat side was the nicotine-stained streak representing one side of the canal.

Upon learning these facts her mistress decided to have nothing to do with her further than to see that she went to hospital. I gave her a note to one of the city hospitals with a brief statement of the facts. She promised to report to me in three weeks' time.

Strangely enough (I had been called from my office for a moment during her second visit), when she left the house and I turned to put my new pipe-stem in a safe place, I found it had disappeared as strangely as it had at first appeared in the woman's uterus, but no doubt through the same mysterious hands.

UNIVERSITY HEIGHTS.

---

## Progress of Medical Science.

**The Employment of Strontium Bromide in the Treatment of Epilepsy.**—In the treatment with strontium bromide of twelve cases of epilepsy that had previously been treated with potassium bromide, Smith (*Lancet*, August 12, 1899, p. 411) found that there was only a slight difference between the effects produced by the two drugs, though what difference there was was clearly in favor of the strontium salt as regards the absolute number of attacks. It was found also that the seizures were in some instances of milder type, while the tendency to the appearance of a bromide rash was much less marked. A larger dose of the strontium salt was required to control the fits, the largest amount of potassium bromide required being an average dose of twenty grains, while it was necessary to give an average dose of thirty grains of strontium bromide to effect the same result. The potassium salt seemed to exert its action more quickly than the strontium salt, for the seizures were controlled after the former drug had been given for five weeks, but it was not until the end of the seventh week that the same result was brought about by the latter. The good effect of potassium bromide seemed to be more lasting than that of strontium bromide, as it was found necessary to increase the dose of the latter at shorter intervals than in the case of the former.

**Tumors of the Pituitary Body.**—Walton and Cheney (*Journal of Nervous and Mental Disease*, August, 1899) report a fatal case of acromegaly in which after death a perithelial angiosarcoma of the pituitary body was found. From a study of the subject they came to the conclusion that congenital peculiarities in growth resembling those of acromegaly, but occurring in otherwise healthy individuals, may point to structural defect of the pituitary gland, a defect sometimes furnishing the starting-point for new-growth later in life. The occurrence of a pituitary tumor without definite symptoms of acromegaly does not necessarily disprove a connection between the organ and the disease, for the persistence of even a small amount of healthy gland-tissue is sufficient to carry on fairly the function of the pituitary body. The combination of general symptoms of new-growth with optic atrophy and loss of temporal field of vision makes the diagnosis of pituitary tumor almost certain. Hemiachromatopsia is not necessarily of central origin.

**The Treatment of Exophthalmic Goitre with Injections of Iodoform Solutions.**—At the French Congress of Medicine recently held at Lille, Pitres stated that he had given up injections of tincture of iodine in the treatment of exophthalmic goitre, as they are sometimes followed by abscesses. In their stead he now employs a solution of iodoform in ether, of which he injects 1 c.c. into the tissues of the goitre at intervals of about eight days. The resulting pain is acute, but it lasts only for about twelve minutes. The nervous symptoms cease, sleep returns, the gland gradually hardens and becomes smaller, and the exophthalmos disappears. Cardiac irritability persists for some time, but the arterial pulsation diminishes and the sense of palpitation disappears. Of twelve cases thus treated six have remained well for more than two years, and of the one hundred and twenty injections made none was followed by any untoward result.—*The Lancet*, August 19, 1899.

**Eye Accidents in the Trades.**—In a paper read by Dr. Simeon Snell in the ophthalmologic section of the last British Medical Association, it is stated that five per cent. of all accidents to miners, rendering them unfitted to continue their work, are injuries to the eye. He advocates the wearing of protectors for this class of laborers as well as for grinders, and iron and steel workers. He describes a gauze shield, and concludes his paper with the following suggestions: (1) The grinder will find that large glasses made of plain glass, or indeed his own spectacles, should his refraction require their use, will afford great protection. Or he may use other protectors made with glass in front and gauze surrounding it. (2) The use of protectors should be compulsory for those workers in iron and steel whose employment renders them liable to be injured by iron or steel splinters, or who are exposed to danger from molten metal.—*British Medical Journal*, August 12th.

**Exceptional Causes of Insomnia.**—Dr. Oppenheim (*Deutsche Medizinal-Zeitung*, July 27th) mentions the following: (1) The psychogenic form of insomnia in which delusions, mental excitement, and severe emotions disturb sleep; delusions of grandeur which generally exacerbate at night. Of the various conditions of fear it is well known that they occur, as a rule, dur-

ing the hours in which the patient does not long for sleep. A fear of not being able to fall asleep is one of the most common forms. The primary form of nervous insomnia belongs in this category; here the continuous emotional and mental excitement prevents the person from falling asleep. Hyperæsthesia of the organs of sense, especially the ear, is another cause of insomnia. An affection of the optic or auditory nerve may also cause sleeplessness. (2) The dolorous form, in which pain of any character, or from whatsoever source, hinders sleep. The warmth of the bed, the change of position, and the circulatory apparatus, as well as personal observation and attention, may cause it. Paræsthesia and itching of the skin may prevent and disturb sleep. There are neurasthenics who suffer intensely at night from a severe pruritus of special parts, particularly the genitals. The same applies to urticaria, as well as to the circumscribed œdema, both occurring as soon as the patient enters his bed. Thermoparæsthesia may also deprive one of sleep. Under this heading comes the paræsthesia of the auditory apparatus, above all the nervous buzzing in the ears, which in many persons occurs just before falling asleep, whereas during the day they are perfectly free. (3) Gastric disturbances. Nervous dyspepsia, flatulence, tympanites, and eructations occur just at bedtime in persons who are entirely free from such symptoms during the day. (4) Cardiac and circulatory disturbances. These modify sleep by palpitation and pulsation of various parts. (5) Secretory disturbances. Hereunder are included hyperidrosis and salivation, which occasionally occur at night. (6) Motor irritations may influence sleep. It is but little known that the fibrillary twitchings may greatly influence sleep. The twitchings begin just at the moment of sleep. (7) Sexual form of insomnia. Under this heading may be mentioned painful erections, which frequently occur during the night.

**Experience in Appendicitis.**—Doerfler (*Wiener medizinische Blätter*, July 27th) says that for practical purposes appendicitis may be divided into the following groups: (1) Appendicitis propria, limited to the appendix without involvement of the peritoneum and characterized by appendicular colic, severe abdominal pain, and pallor. There is no vomiting. After the attack, tenderness in the appendix region and a sausage-like resistance can be felt. This process is to be differentiated from perityphlitis by absence of dulness and peritoneal irritation. Many cases diagnosticated as renal or biliary colic are appendicitis. A tendency to diarrhœa following irregularities in diet often prevails. For that reason a rectal examination is indicated in persons who complain for any length of time of abdominal disturbances. Internal therapy is useless. Rest, regulation of diet, and perhaps laxatives are indicated. A radical cure is effected by removal of the appendix. (2) In appendicitis serosa the inflammation involves the surrounding peritoneum. The attack is characterized by pain, dulness, and a tangible resistance. There is a great tendency to recurrence. The therapy consists in rest and opium. In case of numerous recurrences operation should be done. (3) Periappendicitis suppurativa circumscripta—that is, the circumscribed peritonitis in the appendix region is characterized especially by meteorismus and resistance in the cæcal region; chills, vomiting, and diarrhœa are often absent. The right limb is moved with difficulty and the pulse is frequent. If the exudate increases in size it may pass between the bladder, uterus, and rectum. The final results may be either encapsulation or perforation, entrance into the free abdominal cavity by the way of the lymphatics with resulting subphrenic abscesses, pleurisy, and extra-peritoneal suppurative areas. Treatment is expectant for two or three days, then operation. (4) The generalized suppurative peritonitis following appendicitis cannot at the very beginning be differentiated from the localized form. After the onset the generalized tympanites may perhaps aid in the diagnosis. (5) The acute septic peritonitis is always fatal. It is characterized by a very violent onset, which lasts during the entire course. Early examination under narcosis is necessary, inasmuch as in early operation lies the only hope of recovery.

**The Relations of Alimentary Glycosuria to Disease of the Pancreas.**—As the result of clinical and pathological observations in conjunction with a study of the literature, Wille concludes, in an article in the *Deutsches Archiv fur klinische Medicin*, Nos. 5 and 6, vol. lxiii., that the systematic appearance of alimentary glycosuria is an important diagnostic guide with regard to the existence of disease of the pancreas, and that neither temporary alimentary glycosuria nor absence of the symptom excludes with certainty such disease.

**Prophylaxis in Typhoid Fever.**—Taylor (*Progressive Medicine*) says: (1) Isolate patients suffering from typhoid fever, or at least do not permit them to be treated in a room or ward containing young people who have not previously had typhoid. The warning contains some wholesome advice too often neglected, and sometimes with sad results, because we are persuaded that typhoid is not an air-borne disease, and forget that contiguity favors infection, because precautions will inevitably sometimes be neglected. (2) Nurses for typhoid cases should, if possible, be only such as have had typhoid themselves. In a family the young people should be removed. (3) The floor of the sick-room should be oiled, so as to be impermeable. Carpets and rugs should be removed, and the raising of dust should be avoided by frequent use of a cloth dampened with antiseptic solution. (4) The nurses should wear linen clothes, which they should remove when they leave the sick-room, and in general they should be warned to be circumspect in their relations with others, and especially careful of the utmost details of antisepsis in the matter of the preparation of food and drink for themselves and others.

**The Origin, the Occurrence, and the Significance of the Eosinophile Cells, with Special Reference to the Sputum.**—As the result of a comprehensive study, Fuchs concludes that the eosinophile cells have no uniform mode of origin. They may arise as well from neutrophile granulations as from metamorphosed erythrocytes through a form of phagocytosis. Their development is not confined to any particular part, as they may arise everywhere in all tissues and organs, and they may thus appear everywhere. There is no uniform point of view from which the increase or diminution or eosinophile cells in the blood can be judged, and no especial diagnostic or prognostic significance is to be attached to them. They are diminished in febrile states. The eosinophile cells of the sputum arise probably in the respiratory tract. Diagnostic significance is not to be attached to them with regard to bronchial asthma. They occur in varying number in conjunction with all diseases of the respiratory tract not attended with fever. The view that in cases of pulmonary tuberculosis they furnish an objective guide for the determination of the powers of resistance at the time is not justified. They may be considered as constituting a sort of sanitary police against the invasion of pathogenic microbes of all kinds, and they are, therefore, present in largest numbers in those organs and tissues that are most exposed to injurious influences.—*Deutsches Archiv fur klinische Medicin*, Nos. 5 and 6, vol. lxiii., 1899.

# MEDICAL RECORD:

*A Weekly Journal of Medicine and Surgery.*

New York, September 23, 1899.

## TUBERCULOSIS AND QUARANTINE.

THE new theory of the dangerously contagious character of tuberculosis has now extended its application to a proposed State quarantine against all persons or animals afflicted with the disease. California, it appears, is the first to take a stand in this direction, and a member of its health board has with great apparent seriousness made such a proposition.

The radical character of the measure carries with it enough of sensationalism to be widely quoted by the daily press. If nothing else results from the publication of the views of the official who promulgates them, he will at least receive due credit for an entirely original conception. It is a great pity that other ambitious health authorities have not seized similar opportunities for posing as public benefactors. While such a course might be eminently desirable for political purposes, in insuring a continuance of valuable services to the State, it can certainly not commend itself to a becomingly serious discussion from strictly scientific standpoints. At best it shows only to what extreme of non-sensible application any idea of absolutely quarantining against such a prevalent disease as phthisis can be carried.

If California takes such a stand, why should not each of the other States in its own interests follow suit? What then would become of the poor consumptive, whose right to live somewhere and somehow is hardly to be questioned? The truth is, the present attitude of the new health missionary only proves the danger of snap-shot judgment on a very broad question of utility. It is not to be wondered at that the so-called practical men in our profession are constantly alert in seeking an application for the slightest scientific hint. In the hurry for accomplishing results there is no time for calm discussion of opposite views.

This state of a question was particularly manifest when the ingenious and taking theory of the contagiousness of tuberculosis was first mooted. There was such a very plausible relation of cause and effect with the tubercle bacillus as a controlling factor that there was an irresistible temptation with the majority of the profession to accept the new doctrine without question.

Although, scientifically speaking, the question is by no means absolutely settled, it is considered almost a heresy to take the opposite view, that the bacillus, instead of being a causative element of tuberculosis, may be merely an associated or possibly a resultant condition of the disease. While it is always erring on the safe side to guard against every supposable cause for the spread of disease, it is certainly very difficult to prove by ordinary methods of observation that phthisis is strictly amenable to such laws as generally govern contagious diseases. Until we can be absolutely sure of the latter point, and can give better reasons for our conclusions than at present appear to be possible, it is plainly not wise on general principles uselessly to antagonize the tremendous public interests on the other side.

There are too many object-lessons in every community bearing on the opposite view of actual contagiousness of phthisis to make the public easily convertible to the prevalent professional opinions on the subject. In other words, the public is hardly prepared as yet to take any extreme view. It is willing to be educated, but naturally refuses to be forced. Obviously enough it will be impossible to quarantine against tuberculosis, even if the most stringent laws were enacted to that end. The large number of suspicious persons that it would be necessary to examine, the uncertainties of necessarily hasty diagnosis in incipient cases, and the still larger number of actually diseased persons who would undoubtedly escape any examination whatever, would exemplify a few of the many difficulties which would attend such an absurd innovation.

But these are not all the objections that might be urged against similar measures suggested by over-zealous and misguided extremists. In general all such attempts at bettering existing conditions overreach themselves, make sanitary science ridiculous, and injuriously affect the best-directed efforts of all sound-minded and earnest-working men. The right view of this great question of contagiousness of tuberculosis is somewhere in the middle ground. Is it not possible that there is altogether too much scare in the whole business, and that a little more thought and a little more study may modify present views, and thus make the suggestions for remedial measures correspondingly reasonable and convincingly practicable?

## NERVE TIRE IN THE SCHOOLS.

HALF a million of New York's population is now busily engaged over book and slate. It is no unimportant part of any community's inhabitants, this youthful element for whom each fall the vast machinery of education is set in motion.

Physicians and public-health officials have a duty in the matter which teachers, school commissioners, and parents may at times overlook. All interested in the welfare of the growing generation should pause to consider the question of possible overtraining. A physical or mental wreck is a most depressing sight at any period of life, but a breakdown at the very threshold, when foresight on the part of others might have prevented it, is sad indeed.

No doubt one of the chief causes of nerve fatigue in school children is lack of sufficient fresh air and especially of bodily exercise in it. In the desire to crowd facts and figures into the receptive brain, the instructors, and behind them the commissioners or committeemen, lose sight of that most important fact, that the building of a beautiful character and a physically strong body is the most essential part of the whole education. Where overcrowding prevails in the home life and unhygienic surroundings predispose to conditions of anæmia, the school should all the more endeavor to counteract the evil influences by supplying, so far as possible, the elements of health which are lacking.

Time to breathe a little outside air, time to stretch the muscles, and, above all, time to eat the mid-day meal slowly and to digest it partially before returning to the desk, should be provided.

Dr. Scheidt, who has given much attention to school hygiene, delivered a long address last year before the Associated Sanitary Authorities of Pennsylvania, of which some of the conclusions reached were these:

"(1) I am convinced that the æsthesiometer is the proper instrument for the measurement of fatigue. (2) My tentative experiments with American boys prove a superior normal strength of their mental vigor under favorable conditions of the atmosphere. (3) Unfavorable conditions of the atmosphere show an unusually large percentage of abnormal fatigue of the nervous system. (4) I attribute this condition to the utter lack of systematic open-air exercises. (5) I advocate such exercises for children as a prime necessity, because the foundations of a healthy and useful life are laid between the seventh and fifteenth years, but never afterward. (6) Training of all the functions of the physical organism should precede instruction, because it will develop the necessary mental strength. (7) Children should be classified according to their individual characteristics, and stress should be laid upon the development of their weakest organs, in such a way, however, as to leave plenty of room for individualization. (8) Such exercise should take place every afternoon, and should be continued until the limit of normal fatigue is reached. (9) The exercises should be grouped into muscular, cutaneous, and respiratory. (10) All these exercises should be essentially exercises of the nervous system, to lead to a proper development of character."

Speaking of the part the physician should take in this matter, Dr. Scheidt says: "The chief factor in every school board should be the well-trained physician." When this suggestion is adopted we may look forward to a lessening of that nerve fatigue, irritability, and final collapse which is so often brought about by poor digestion, absence of open-air playground, and the punishment by "keeping in." Of all barbarous practices, that of allowing twenty minutes for a cold lunch, and then detaining a young child after hours in a vitiated atmosphere because indigestion and beginning dyspepsia have produced irritability and inattention, is the most fruitful source of nervous weariness which sooner or later leads to the physical wreck.

## YELLOW FEVER IN CUBA.

The first fruits of our war with Spain are already being gathered, and Cuba bids fair ere long to be wholly free from yellow fever. If this wished-for consummation is indeed brought about—and there seems every reason to hope that such will be the case—then, even if no other advantage is gained this country will not be without its reward for having waged the humane war. Havana, owing to its proximity to this country and to the considerable trade between that port and the United States, has for many years been the means of disseminating yellow fever among the inhabitants of the mainland, and a constant menace to health. Possibly no city in the world so fully deserved the name of "pest hole" as Havana. Its very soil reeked of disease germs, and while the Spaniards remained in occupation of the island there was but little chance of bettering matters. Since the Americans have been in charge of affairs a marvellous change in the situation has taken place, and the statistics illustrating this improvement are eloquent in their simplicity.

In a letter from Havana to the *Evening Post* it is stated that "there have been within the last few months from twenty-five hundred to four thousand cesspools cleaned and disinfected and many of them entirely closed up. All public places, such as hotels, cafés, theatres, etc., have been carefully inspected and thoroughly cleaned and disinfected. . . . The twenty-seven thousand houses in Havana, Regla, and Guanabacoa have been thoroughly inspected throughout and proper sanitary measures taken for their cleanliness and disinfection. . . . All throwing of refuse from the slaughter houses into the harbor has been stopped, and all the city refuse is disinfected with chloride of lime. . . . The city garbage is cremated as much as possible, and the remainder not cremated is towed out to sea some three miles and dumped into the Gulf Stream. Spitting on the floor of public places has been forbidden, and a great deal of the pavement has been relaid. In fact, every method suggested by human ingenuity to ameliorate the sanitary condition of the city has been intelligently and efficiently carried into effect. The result of these drastic measures has been as satisfactory as the most sanguine could have wished. The deaths from yellow fever in 1896 were 1,539; in 1897, 1,056; from 1890 to 1894, under normal conditions, they averaged 400 a year." In the present summer the number of cases of yellow fever has been smaller than for years past. When the fact is taken into consideration that up to the time of the American occupation the city had been filled for three years by sixty thousand Spanish troops, of most filthy habits, and that neither they nor the inhabitants practised any sanitary precautions, the alteration effected in so short a time must be looked upon as remarkable. To General Ludlow and to Major John G. Davis, the correspondent we have quoted says, the credit for the partial hygienic conversion of Havana is chiefly due. Of course much yet remains to be done before Havana can rank as a healthy city, but the success attending these first steps toward sanitary reform has plainly shown that it can and will be regenerated.

## THE TEACHING OF ANATOMY.

To those who are familiar with the present method of teaching anatomy in our prominent medical schools, the thought must often have occurred that perhaps too much was being required of the student, and that the utility of this forcing process was somewhat doubtful, even if it was apparently successful. In the schools of which we are speaking, the students are now taught anatomy didactically and practically, and also histology, chiefly a course in microscopy with no set lectures. Between the anatomy which can be and is taught in the dissecting-room and by lecture, and histological anatomy, there lies a borderland in the subject which might be called laboratory anatomy. This includes the coarse structure of the brain, the organs of special sense, and some other parts. The microscope is not needed for the study of the ordinary anatomy of these structures, but close examination is required, and demonstration cannot be made to a large number of students simultaneously. It is in such, and some other localities, that so much of the increase in instruction in minute details lies, and it is also here that anatomy of the least practical value is taught. The attempt is made at present in our schools to cover the whole subject of anatomy, both gross and semi-microscopic, in the course labelled in the college catalogue, "Anatomy," and the students are required to be prepared upon the whole of the mass of detail which must necessarily be presented to them, regardless of what their future work in medicine is to be. They are thus compelled to acquire, temporarily at least, an enormous number of facts which are for the majority of them useless and promptly forgotten. The minute structure of the internal ear or of the otic ganglion is of no use to a man who intends to practise general medicine or surgery, and he might much better spend his time in a dispensary learning how to treat a scalp wound or a paronychia in the proper way, than in learning the fine points in the structure of the sympathetic system or of Meckel's ganglion. If he should learn all that is known on those subjects, his knowledge will not survive many months, and in a year or so he will probably not retain even a general idea of them. We know that, as a general statement, the acquisition of knowledge upon any subject is desirable, but for those who are preparing to practise medicine at the present day, we must recognize the fact that some knowledge is worth more than other knowledge, and also that individual needs should be considered. In many schools of learning subjects are divided into "major" and "minor," the former taken up by those to whom an extended knowledge of the subject is going to be useful. The "minor" is taught no less accurately and thoroughly, but simply less extensively. Anatomy is of course, with physiology, the foundation of medical science, but it is becoming inexpedient for the student of medicine to be an anatomist to the extent now required, at least ostensibly, in most schools. When the graduate leaves college, he should have a complete knowledge of anatomy to the extent that it is taught in such books as Gray, Morris, or Gerrish, and it is not necessary that he should have been required to sit through lectures or demonstrations in which are quoted anatomical refinements such as are offered in books like Schwalbe's "Anatomy of the Nervous System." Such works can barely be skimmed over, and the mind of the student is temporarily clouded with a mass of indistinct detail, only to resume very soon its pristine freedom from any knowledge of the subject. These works are mines of information for the man who wishes to learn all that has been done in special fields, but are unnecessary to any but such advanced workers. The microscopic structure of tissues and organs is of great importance, and is, as a rule, very well presented to the student. The work in the dissecting-room is also carried on successfully, but in this middle field, the existence of which we have suggested, there is room for reform and reorganization, so that there may be no risk that the future physician will, in his efforts to acquire an exact knowledge of the cochlea, omit to learn the anatomy and relations of the stomach and liver.

## PERIPHERAL NEURITIS AND LOSS OF KNEE JERKS IN DIABETES.

However induced, diabetes usually manifests itself as a metabolic disturbance characterized by defective assimilation of carbohydrates and the more or less constant presence of glucose in the urine. The symptoms present vary widely in accordance with the intensity of the morbid process. Early in life the disease exhibits a peculiar virulence, being usually rapid in course and fatal in termination, while after middle life its existence may not be suspected until routine examination of the urine discloses the presence of grape sugar. Next to the nutritive failure, which is, after the glycosuria, perhaps the most distinctive, as it is the most important, symptom, the toxic manifestations of diabetes are of greatest interest. These have received considerable attention in late years, and it may be hazarded that they are not due to the presence and action of the sugar in the blood or of the substances that are responsible for its presence in the urine, but rather to the activity of certain of its decomposition products. The most serious of these toxic accidents of diabetes is the fatal coma indicative of the overwhelming of the nervous system by the poisons generated in consequence of the deranged metabolism. Among others is peripheral neuritis, with its varied manifestations, some of which have been investigated by Grube (*The Lancet*, July 22, 1899), who in a study of three hundred and ten cases of diabetes found the knee jerk lost in eighty-four (27.1 per cent.) and preserved in two hundred and twenty-six. The proportion of cases in which the reflex was absent increased in general with advancing age, and it is believed that the loss is due to nutritive changes in the nerves as a result of arterio-sclerosis. The knee jerk was lost in 49.1 per cent. of the cases of mild diabetes and in 23.9 per cent. of those of severe diabetes. In sixteen cases—three severe and thirteen mild—the knee jerks were unequal. Increase in the knee jerks was ob-

served in five severe cases, in consequence of the general debility; and in six mild cases, from various other causes. Peripheral neuritis was observed in seventeen cases, being associated in two with increased knee jerks; in four with abolition of the knee jerks on one side; and in eleven with such abolition on both sides. Most of these patients were men; all but one were over fifty years of age and represented mild cases. It was noted, further, that a large amount of sugar is generally present at the beginning of diabetic neuritis, but when the nerve inflammation has once been set up it runs its course independently and apparently without being influenced by the treatment directed against the diabetes. The frequent occurrence of cramps in the legs in diabetic patients is considered as indicating that the amount of sugar circulating in the blood has an influence on the nerves. The cramps appear early when the amount of sugar is large, they disappear when this has been reduced, and they are prone to recur when an increase in the amount of sugar takes place. It is suggested, further, that the impotence manifested by so many male diabetics is also probably caused by nutritive changes in the nervous apparatus concerned.

Williamson (*Medical Chronicle*, November, 1892, and *The Lancet*, July 17, 1897) found the knee jerks absent in about fifty per cent. of one hundred cases of diabetes. He attributed the disparity in the results recorded by different observers as to the frequency with which diabetes mellitus is attended with absence of the knee jerks to the varying character and severity of the cases, the stage of the disease at which the observation is made, and the age of the patient. Williamson believed the association to be more common in severe than in mild cases, and late rather than early in the course of the disease. He further found it present in 76.9 per cent. of cases, in patients under the age of thirty years—when the disease is admittedly more serious than later in life—and in but 40.9 per cent. of those in patients over thirty years of age. The natural conclusion to be drawn from these observations appears to be at variance with that to which those of Grube lead, namely, that absence of the knee jerks is more common in mild than in severe cases of diabetes.

**A Race of Giants.**—It is reported that a captain in the British army named Welby has recently returned from an expedition in the unknown portions of Abyssinia and the countries lying north of Uganda between Lake Rudolf and the Nile valley. He visited and lived among some twenty different tribes, several of which are quite new to explorers. Perhaps the most curious of these were two races of giants said to be seven feet in height, living near Lake Rudolf. Some doubt has been cast on the veracity of Captain Welby in regard to his assertion as to the height of these people; but it should be remembered that the dwarfs discovered by Stanley were regarded by many persons as a myth until the account was verified by other explorers. The Patagonians too, although not averaging seven feet in height, are very tall.

## News of the Week.

**Illegal Practitioners in Wheeling.**—The physicians in Wheeling, W. Va., have undertaken a crusade against all who practise without a degree. At a special meeting of the State Medical Society a committee was appointed to raise funds for this object. Not only will Christian Scientists and other charlatans be prosecuted, but an effort will be made to correct abuses arising under the old State laws by which licenses are granted to unqualified and often ignorant persons.

**Pathological Society of Philadelphia.**—At a stated meeting held September 14th, Dr. W. E. Hughes exhibited a specimen of gumma of the heart from a child twenty-two months old with a syphilitic heredity. The new formation was situated in the interventricular septum just below the division between the auricles. Dr. Joseph Sailer exhibited sections from a case of hypertrophic cirrhosis of the liver, and specimens of fatty and contracted kidney with dilatation of the ureters and pelvis of obscure origin and with hemorrhagic pericarditis. Dr. William E. Robertson exhibited a specimen and sections of osteo-sarcoma of the femur, following traumatism; and a specimen and sections of a mixed tumor of the testicle.

**Yellow Fever.**—Up to September 20th, there have been reported over four hundred cases of yellow fever with about twenty deaths at Key West. From twenty to forty new cases occur each day. At New Orleans one new case of yellow fever was reported on September 18th, making ten cases in all since the disease first appeared. Two cases have resulted fatally, five terminated in recovery, and three patients are suffering from a mild attack and are expected to recover. Both Charleston, S. C., and Augusta, Ga., have declared a quarantine against all towns where the fever has been reported to exist. Sporadic cases are reported now and then as occurring in Santiago de Cuba, and there were two deaths there this week. A passenger on a steamer from New York to Havana was found on arrival at the latter place to be suffering from yellow fever. How the disease was acquired is a mystery, unless perhaps the ship had become infected at Vera Cruz, or some other Mexican port, the weather after her return to New York having been too warm to kill the virus.

**Typhoid Fever in Europe.**—An epidemic of typhoid fever has broken out in the Moabit quarter in Berlin, but the disease is reported to be less prevalent in Paris than it was in August. In Madrid there is also quite an epidemic, fifty-nine cases of typhoid fever having been reported there in one day last week. Since the outbreak of the epidemic, however, the disease has been in mild form, the proportion of cases resulting fatally being small.

**Dr. Alonzo E. Taylor,** assistant director of the Pepper Laboratory of the University of Pennsylvania, has been elected professor of pathology in the medical department of the University of California.

**The Smoke Nuisance.**—The beauty of New York City is being gradually ruined by the volumes of soot poured out from the chimneys of factories, power-houses, and hotels where soft coal is used. The board of health is constantly issuing notices to the press of the work of its lynx-eyed detectives in unmasking the users of soft coal when the air for blocks around is filled with black smoke, but the nuisance goes on. Its latest pronunciamento is that the president of the health board has "sent instructions to the assistant sanitary superintendent of the Borough of Queens to notify the owner of every factory or other place which is at present violating the smoke ordinances that the nuisance must be stopped forthwith. Superintendent Lusk was instructed to proceed against every offender who has had the five days' notice required by law, and cause his arrest. The Long Island Railroad Company will have to comply with the ordinance the same as the factories and other buildings." It is dollars to doughnuts that more soft coal will be used in New York next month than this, and next year than this, so long as the present commissioners are in authority.

**Rabies in Western New York.**—An epidemic of rabies has existed all summer in Erie County, N. Y., and the efforts of the officials to suppress it have hitherto failed. An investigation undertaken by an inspector from the office of the State commissioner of agriculture shows that about the middle of May last a strange dog bit several dogs in the neighborhood of Morton's Corners, in the town of Collins, Erie County, and that this dog covered an area of seven or eight square miles and was finally shot. The dogs that were bitten were chained up at the time, and in seven or eight days developed a disease believed to be rabies. Two of the bitten dogs were killed, while another got away about the middle of June and was afterward found about ten miles away by the owner. It was brought home and died the next day. Another of the dogs also got away about June 15th, disappeared, and has not been heard from since. In all, one man, one child, fifteen cattle, two horses, six hogs, and a large number of dogs have died with supposed rabies, and five or six persons have been sent to this city for anti-rabic treatment. The commissioner of agriculture has now ordered a quarantine against rabies in every town in Erie county, including Buffalo. The terms of the quarantine are that all dogs and other domestic animals susceptible to rabies shall be kept secluded for sixty days.

**More Bicycle Insanity.**—A silly woman has just ridden on a bicycle a distance of seven hundred miles, on Long Island roads, in eighty-one hours and five minutes. Besides being supremely foolish, this young woman's act was also criminal, the law distinctly forbidding tests of the kind continued through more than twelve hours out of the twenty-four.

**Smallpox** has broken out among the troops about to start from San Francisco for Manila. On September 20th there were three well-developed cases of smallpox and fourteen suspected cases in the quarantine hospital at the Presidio, San Francisco. Five of the suspects showed almost unmistakable symptoms of the disease. All the patients are members of the Thirty-first Regiment.

**Tuberculosis Quarantine.**—The attempt of the California State board of health to establish a quarantine against human beings and domestic animals suffering with tuberculosis is not likely to be imitated elsewhere. The quick-witted inhabitants of Arizona have already issued a statement that the climate of that State is so dry and pure that there can be no reason whatever to fear the spread of tuberculosis there.

**The Plague.**—Reports of the prevalence of the plague come from many and widely separated parts of the world. In India there has been a falling off in the number of new cases and of deaths, but in Hong Kong there are about twenty deaths a week. The premier of Cape Colony announces that the disease exists at Magude, Delagoa Bay, in most virulent form, every one of the forty-two persons attacked up to September 14th having died. A dispatch from Buenos Ayres, dated September 18th, states that the bubonic plague has broken out at Asuncion, the capital of Paraguay.

**The Mississippi Valley Medical Association.**—The annual meeting of this association will be held at Chicago, Ill., on October 3–6, 1899, under the presidency of Dr. Duncan Eve, of Nashville, Tenn. The secretary is Dr. Henry E. Tuley, of Louisville, Ky. The address in medicine will be given by Dr. J. A. Witherspoon, of Nashville, and the address in surgery by Dr. Lewis S. McMurtry, of Louisville. The programme gives the titles of about sixty papers. This association was founded as the Tri-State Medical Society of Indiana, Kentucky, and Illinois, but gradually membership was extended to the citizens of other States, and even the limits of the Mississippi Valley have been passed, the meetings being attended by physicians from east of the Alleghanies and from as far west as Utah. Indeed the society is rapidly occupying national territory and threatens to rival the American Medical Association. At the meeting in Louisville in 1897 definite organization was adopted, including constitution and by-laws. The most important change was made in the membership, which became continuous, dependent upon regular payment of dues, two years' non-payment causing forfeiture. The first meeting was held in Vincennes, Ind., in 1875. In honor of the association and for the convenience of its members a series of about one hundred and forty public clinics will be given at the various hospitals and dispensaries from September 25th to October 2d, and from October 7th to October 14th.

**The New Dispensary Law.**—These be parlous times for the so-called medical charities, between the comptroller's determination to cut them off from the public crib and the coming into force on October 1st of the amended dispensary law. This law defines a dispensary as "any person, corporation, institution, association, or agent whose purpose it is, either independently or in connection with any other, to furnish,

at any place or places, to persons non-resident therein, either gratuitously or for a compensation determined without reference to the value of the thing furnished, medical or surgical advice or treatment, medicine or apparatus, provided that the moneys used by and for the purposes of said dispensary shall be derived wholly or in part from trust funds, public moneys, or sources other than the individuals constituting said dispensary and the persons of said dispensary actually engaged in the distribution." All dispensaries must be licensed, and each applicant, before he receives a license, must swear that the dispensary is for the benefit of the public, and no one can conduct a dispensary without this license. The license shall not dictate any school of medicine to be practised in the dispensary, but the board of State charities is empowered to visit and examine every dispensary and to revoke a license after due notice if it finds that the law is being violated. The law forbids the carrying on of a dispensary in a tenement house or in connection with an apothecary shop. Any person who violates the law is guilty of a misdemeanor, punishable by a fine of not less than $10 and not more than $250. The same fine is fixed as the punishment of any one who obtains dispensary relief by false representations of poverty or inability to pay for medical advice. According to the "Medical Directory" for 1899, there are eighty-eight dispensaries and infirmaries in Greater New York, but if the drug-store dispensaries and similar places are included this number will be more than doubled.

**Hunting in Hawaii.**—Dr. Nicholas Senn, of Chicago, has returned from the Hawaiian Islands with a weird tale of the game conditions on the island of Molokai. Deer are so numerous that when it comes to velvet time they kill the trees by rubbing their horns; and professional hunters from California have been imported to destroy the deer and save the forests. This fable teaches that when it comes to expert tall talk in hunting stories, we have nothing to teach the native talent of the Hawaiians.—*Forest and Stream.*

**A New Harlem Hospital.**—President Keller of the Charities Department has asked the board of estimate to include $474,500 in his appropriation for 1900 for alterations and repairs to buildings. This sum is $274,500 in excess of the amount appropriated for the same purpose last year. Among other things to which the money will be applied is the building of a new Harlem hospital, which will cost $150,000.

**The "Relief" Unseaworthy.**—The steamboat inspectors of San Francisco have condemned the hospital ship *Relief* as unfit to carry passengers on the ocean. The boat was about to sail for Manila with twenty women nurses and one hundred men of the hospital corps in addition to her regular staff. The War Department ordered an investigation, and the report of the board has been received. In it the board says that "although of the opinion that the ship is structurally strong enough to make the voyage, recommends that she be sent on her proposed voyage with her officers and crew only; that the passengers (nurses and men of the hospital corps) be not taken in the ship, but sent to Manila by some other means; that sufficient of her cargo be removed and the space so gained be filled with additional coal; that the voyage be made via Honolulu and Guam to avoid possible rough weather, and that the ship be retained in the Philippines and not used for long ocean voyages or for voyages in the season when storms may be expected." The hospital corps men and nurses will be sent on another vessel.

**Navy Department,** Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending September 16, 1899. September 8th.—Surgeon M. H. Crawford detached from the marine recruiting rendezvous, Chicago, Ill., and ordered to the marine recruiting rendezvous, New York, N. Y.; Passed Assistant Surgeon E. S. Bogert detached from the marine recruiting rendezvous, New York, N. Y., and ordered home and to wait orders; directed to be ready for orders to sea duty; Passed Assistant Surgeon J. M. Moore detached from the *Vermont* and ordered to the marine recruiting rendezvous, Chicago, Ill.; Assistant Surgeon M. S. Elliott detached from the marine recruiting rendezvous, New York, N. Y., and ordered to the *Vermont;* Assistant Surgeon W. M. Garton detached from the *Franklin* and ordered to the Washington navy yard. September 11th.—Surgeon P. A. Lovering ordered to duty at the recruiting rendezvous, Buffalo, N. Y.; Passed Assistant Surgeon W. F. Arnold ordered to the Pensacola navy yard; Passed Assistant Surgeon H. N. T. Harris detached from the Pensacola navy yard and ordered home and to wait orders; Assistant Surgeon J. S. Chaffee, resignation accepted. September 13th.—Medical Director J. R. Tryon detached from duty as general inspector of naval hospitals and ordered home and to wait orders; Assistant Surgeon E. C. Parker detached from the Pensacola and ordered to the *Hartford.* September 14th.—Medical Director J. R. Tryon retired September 24th; Passed Assistant Surgeon L. L. Von Wedekind granted sick leave for three months, when discharged from naval hospital, Mare Island, Cal.

**Obituary Notes.**—Dr. Robert B. Cruice died suddenly at Philadelphia on September 14th, at the age of sixty-one years. He was graduated from the medical department of the University of Pennsylvania in 1859, and he entered the army as an assistant surgeon in 1861, retiring from the service in 1863, after injuries resulting from a crush by a horse. He later became house surgeon and subsequently physician and surgeon in charge and in 1894 president of the medical staff of St. Joseph's Hospital.—Dr. Karl Stoerk, professor of laryngoscopy and rhinoscopy at the University of Vienna, died on September 14th. He was born in December, 1852.—Dr. William H. Taggart, of Philadelphia, died on September 20th, in a sanatorium at Wernersville, of Bright's disease. Dr. Taggart was born in 1829. During the Civil War he served with distinction as regimental surgeon.

## Therapeutic Hints.

**Summer Diarrhœa in Infants.** — As summer diarrhœa is so apt to be of a putrefactive nature, all agree upon the necessity of completely clearing out the gastro-intestinal tract as a necessary start in treatment. In most cases when the physician is called, the stools are loose and there may be vomiting. By at once stopping all milk, the stomach is soon emptied, and the principal indication is to clear out the bowel. If vomiting continues, draughts of tepid water may be administered, which, when rejected by the stomach, wash out that organ. I do not believe it is often necessary to wash out the stomach with a tube. Sometimes when there is excessive irritation of the stomach, with much production of mucus, one washing out, however, will give relief. I usually employ tablet triturates of calomel, gr. $\frac{1}{10}$, every hour until six or eight have been administered. These small doses act as a sort of a stimulant to the bowel, increase glandular activity, and usually effectively clear out the canal of its fermenting contents. The drug is also supposed to have some antifermentative effect. A good-sized dose of castor oil is also effectual, and is followed by a sedative effect on the mucous membrane. The drug that I have found most useful in the summer diarrhœa of infants is the subnitrate of bismuth in large doses. As far as I have observed, the subcarbonate, salicylate, and subgallate of bismuth and beta-naphthol bismuth have no decided advantage over the subnitrate, which is everywhere procurable. — Dr. Henry Dwight Chapin, in *The Medical News*, July 15, 1899.

**Constipation in Infants.**—Constipation in infants is the practitioner's bugbear. He recognizes the inadvisability of the habitual administration of laxative drugs to the young, but is often driven to countenance their use by the paucity of the resources at his disposal. It is important to bear in mind that constipation in infants is due, in a large measure, to the element casein, which, if it is present in milk in larger quantities than normal, as compared with the fatty elements, tends to interfere with the due performance of the digestive functions. A child fed on normal casein, but with a low portion of fat, will probably be constipated. In breast-fed children it does not follow that the proportions of casein and fat are normal, for the maternal supply may be faulty in this respect. Disturbances of health, especially in the direction of indigestion on the part of the mother, will necessarily be reflected in the composition of the lacteal secretion, as can be demonstrated by analysis. The first step, therefore, must evidently be to regulate the habits and life of the mother. She must be placed on a diet of fresh meat, fresh vegetables, and freshly cooked fruit, with due provision for regular exercise and restriction in the matter of tea drinking and other dietetic irregularities. This *régime* will diminish the proteid and increase the fatty constituents of the milk, and will go far to rid the infant of the tendency to constipation. Should it fail, the best treatment for the child is the administration of cream in doses of from one to two teaspoonfuls in warm water from time to time just before the periodical meal.—*Medical Press and Circular*, July 5, 1899.

**Enteric Fever.**—Dr. William Cecil Bosanquet, in an article on "Notes on Two Hundred and Fifteen Cases of Enteric Fever" (Charing Cross Hospital) published in the *British Medical Journal*, July 8th, refers to the treatment employed as follows: "As a rule, treatment was expectant and consisted of liquid diet, absolute rest, and attention to symptoms. The routine medicine was dilute hydrochloric acid, with syrup of orange and water. Excessive fever was treated by tepid, cold, or iced sponging. Ice-cradling was also employed with less visible benefit. In one case treated by raising the bedclothes on a cradle, the patient died of double pneumonia. Antipyretic drugs were not frequently used, with the exception of quinine, which appeared beneficial in some cases. Of antiseptics, turpentine was most frequently relied upon, and was taken well in most instances. The same cannot be said of naphthalene, which frequently caused sickness. In at least one case the pills in which it was contained were persistently passed in the motions unaltered. Antityphoid serum was used in a few cases without visible effect. In one of these cases a relapse subsequently occurred."

**Septicæmic Infection Treated with Antistreptococcus Serum.**—Dr. J. Mitchell Bruce (*British Medical Journal*, July 8, 1899) reports one case of septic endocarditis in the treatment of which the use of the antistreptococcus serum was entirely successful. The conclusions drawn from the one case are: (1) That antistreptococcus serum may succeed in septicæmia after ordinary means have failed; (2) that it may act with great rapidity, all the phenomena disappearing in the course of forty-eight hours. He also reported a case of septicæmia of the cerebrospinal-fever type, from which case he drew the following interesting conclusions: (1) As before, that in some cases of a septic kind antistreptococcus serum is successful; (2) as before, that the effect may be extremely rapid; (3) that success may be attained after other measures have failed; (4) that success may be attained with one serum, after another serum has failed. He advised that one should not be content with one serum if it proved unsuccessful.

**Plastic or Croupous Bronchitis.**—Treatment divides itself under two heads: (1) means used to loosen and dislodge the plugs; (2) to prevent their recurrence. The employment of emetics seems rational, but unless the fibrinous casts are already lying loose, it is difficult to eject them by inducing vomiting. Besides, as we have no exact means of knowing when the plugs have become so thoroughly loosened that they can be thrown off, it is, on the whole, the wiser plan not to administer emetics. Various inhalations, medicated and otherwise, have been suggested, but in my experience I cannot say that any of them were of the slightest service. I regard the treatment of plastic bronchitis as, generally speaking, unsatisfactory. Nothing short of expulsion of the casts gives relief. Lime-water or lactic-acid sprays and inhalations, also solution of the alkaline carbonates, are not more reliable. The internal administration of iodide of potassium with or without expectorants gives as good results as anything. Ewart recommends the cautious intratracheal injection of oil, or a mild solvent such as lime water or trypsin. To prevent recurrence I know of nothing better than the employment of such means as will improve the general health, living in a dry, bracing atmosphere, good food, the internal administration of tinct. quin. ammoniat., nux vomica, and cascarilla, with or without cod-liver oil.—Dr. Thomas Oliver, in the *British Medical Journal*, July 8, 1899.

**Inhalations of Oxygen in Morphine Poisoning.**—Dr. Playfair (*Lancet*, No. 3,913, 1899) successfully treated with inhalations of oxygen a case in which thirty grains of the acetate of morphine had been taken. Several hours after oxygen inhalations were made, followed by hypodermic injections of atropine and strychnine, and strong coffee and brandy were given. This treatment was continued for nearly ten hours, with complete recovery of the patient. The

author is of the opinion that oxygen not only acts as a direct heart stimulant, but possesses some oxidizing effect on the poison.

**Arsenic in Typhoid.**—According to Dr. Wilson (*La Semaine Médicale*, No. 1, 1899), arsenic is an excellent intestinal antiseptic in typhoid, and when given from the outset of the disease shortens its duration. He uses the following formula:

| | |
|---|---|
| R Ammon. chloridi | 16 gm. |
| Liq. Fowleri | 4 " |
| Aq. destill | 120 " |

M. S. One coffeespoonful every three or four hours.

Treatment should be continued for a short period after the fever has abated.

**Sea-Sickness.**—When I have the chance to advise prospective voyagers, I always insist on careful diet for several days before going to sea, and a liberal calomel and saline purge about forty-eight hours before sailing.—P. K. TAYLOR.

**Lime in the Eyes.**—Washing out the eye immediately with a solution of sugar water is said to stop the pain at once, and lessen the danger of permanent injury. The sugar enters into a chemical combination with the lime, which loses its caustic properties.—*Monatsch. für Hom.*

**Important Tips.**—1. The value of small doses of tincture of aconite frequently repeated in the treatment of amygdalitis and in the initial stage of febrile diseases.

2. The value of painting the chest and back with liquor iodi fortis—diluted if necessary with an equal quantity of the tincture—in all cases attended with cough.

3. The value of a pill of exsiccated ferrous sulphate in conjunction with the administration of purgatives in the treatment of anæmia.

4. The value of grain doses of gray powder with an equal quantity of Dover's powder from three to six times a day in the treatment of syphilis.

5. The value of large doses of the iodides in the treatment of tertiary syphilis.

6. The value of large doses of bromide of potassium in the treatment of the "heats and flushes" and other symptoms from which women suffer about the time of the menopause.

7. The value of large doses of quinine in the treatment of supraorbital neuralgia, and in the periodical febrile disturbances from which old malarial patients suffer.

8. The value of five grains of butyl-chloral-hydrate with one two-hundredth of a grain of gelsemin in neuralgia of the fifth nerve.

9. The value of small doses of a saturated solution of camphor in alcohol in the treatment of autumnal or choleraic diarrhœa.

10. The value of small doses of perchloride of mercury in the treatment of infantile diarrhœa when the stools are green, slimy, and offensive.

11. The value of sulphide of calcium in doses of a tenth of a grain in the treatment of boils, carbuncles, and abscesses.

12. The value of nitroglycerin and nitrite of amyl in the treatment of angina pectoris and allied conditions.

13. The value of alcohol in the treatment of fevers.

14. The value of flying blisters in typhoidal conditions.—WILLIAM MURRELL.

**Morphinism, Preventive Treatment.**—I do not advise that physicians should no longer make morphine injections, nor even to lessen the number of prescriptions of morphine; this would be to deprive ourselves of one of our best remedial agents in certain cases. But I believe there would be far less morphiomaniacs if, on the one hand, physicians would always insist on themselves making hypodermic injections of morphine for their patients, never entrusting their syringe and morphine to anybody; and if, on the other hand, pharmacists would never fill a prescription for morphine, except the exact number of times indicated on the blank, and once only when there is nothing stated to the contrary. I am convinced that this very simple rule would virtually put an end to morphinism, without depriving us of a precious remedy which is discredited, indeed though unjustly, by reason of the abuse that has been made of it.—ZABACO, quoted in *The National Medical Review*, December, 1898.

**Neuralgia of the Trigeminus.**—

| | |
|---|---|
| R Ext. cannabis indicæ | 0.50 cgm. |
| Acidi salicylici | 5.00 gm. |

For ten cachets. S. One three times a day.

—HIRSCHKRON.

**To Produce Abortion** it suffices for the pregnant woman to remain fifteen minutes in a newly painted room, showing the power of turpentine.—*Maine Journal of Medicine and Surgery.*

**Blennorrhagic Orchitis.**—Applications of salicylate of methyl—twenty drops allowed to fall upon the enlarged scrotum, suspended by a strip of firm material stretched between the thighs, three times daily, covered with impermeable dressing, and over this layers of cotton.—PAUL CAZIOT, *Gaz. Hebd. de Méd. et de Chir.*, February 19th.

**Influenza.**—In over four hundred cases hydrochlorate of phenocol (a combination of phenacetin and glycocol) was employed with decrease of temperature, disappearance of headache, and gradual disappearance of the phenomena. Adult dose, 2 to 3 gm. daily, and in children 1 gm. in divided doses.—VILLANI, *Gaz. Med. Lombarda*, No. 51, 1898.

**Genital Vegetations.**—Dust with pure resorcin or paint on with a brush slightly moistened, and cover with a dry dressing. Repeat daily until lesions fall off. In multiple sessile growths on the prepuce, glans, banalo-preputial fold, about the vulva, etc., paint with ten-per-cent. resorcin in collodion or apply in twenty-per-cent. strength in oil. When the skin is dry, as over the labia majora, a fifty-per-cent. resorcin collodion may be used.—SILBERMINTZ.

**Motor Insufficiency of the Stomach.**—The treatment comprises: (1) The removal, as far as possible, of the etiological factor. (2) A system of dietetics which gives an adequate functional activity to the stomach, followed by a sufficient period of rest with due regard to the general nutrition of the patient. A large number of laboratory experiments and clinical observations have convinced me that two meals a day of properly prepared and suitable food meets this indication far more perfectly than does the frequent-meal system. (3) Medical treatment, or the use of drugs. (4) Mechanical treatment, comprising: *a*, lavage by the direct method; *b*, intragastric douching; *c*, lavage by the indirect method, protecting the mucous membrane from direct contact with the water by means of a thin rubber bag; *d*, pneumatic gymnastics by intermittent distention and contraction of the stomach by the use of cold or heated air; *e*, gyromele, and *f*, intragastric electrization. (5) General treatment: 1. *a*, physical exercise; *b*, H-extension movement; *c*, outdoor exercise; *d*, massage. 2. Rest method. 3. Baths: *a*, hot and cold general full bath; *b*, foot baths; *c*, sitz baths. —FENTON B. TURCK, *Journal of the American Medical Association*, February 4th.

# Society Reports.

## INTERNATIONAL CONGRESS OF GYNÆCOLOGY AND OBSTETRICS.

*Held in Amsterdam, August 8, 9, 10, 11, and 12, 1899.*

(Special Report to the MEDICAL RECORD.)

### OBSTETRICAL SECTION.

*Third Day—Thursday, August 10th.*

(Continued from page 423.)

**Ovarian Pregnancy.**—DR. CATHERINE VAN TUSSENBROCK, of Amsterdam, read a paper with this title. She began by quoting from Dr. J. Clarence Webster's work on "Ectopic Gestation" the statement, "There is no proof that a pregnancy has ever started in a Graafian follicle." This proof she purposed to give. The case was one diagnosed as ruptured ectopic pregnancy by Dr. Kouwer, of Utrecht, and operated upon by him: A woman, aged thirty-one years, Vpara; she had never had a miscarriage nor any previous pelvic disturbance. At the laparotomy, a great quantity of dark blood gushed forth; the uterus was soft and somewhat enlarged; the left ovary and tube were normal. In the region of the right ovary was found a tumor as large as a walnut, to which blood-clots adhered. The right ovary and tube were removed. From the fourth to the seventh day after operation great pieces of decidua were expelled with labor pains. She made a good recovery. In the specimen exhibited the tube was quite normal; the fimbriæ were somewhat conglutinated, but the lumen was free. Pathological adhesions between the ovary and tube did not exist. From the ovary arose a round tumor, with a broad pedicle, of the size of a walnut. Near its top was an opening which was filled up by a clot at the time of operation. It was hardened in Müller's fluid and preserved in alcohol, and then sectioned in the median line through the opening mentioned. The gestation sac in the tumor was thus cut in half, and an embryo appeared of almost 12 mm. length, fixed by a short and thick umbilical cord. The amnion lay loosely attached to the inner surface of the gestation sac. Dr. van Tussenbroek then went on to say that the demonstration of an ovarian pregnancy in this case, almost certain from macroscopical appearances, was proved by her microscopical sections. These she then demonstrated. As remnants of the corpus luteum were found in the whole periphery of the ovisac, we must conclude that the ovum had developed in a Graafian follicle, which, after rupture, had undergone the well-known metamorphosis into a corpus luteum. Decidual transformation of the connective tissue in the ovisac was nowhere to be found; and therefore Webster's decidual reaction was not a *conditio sine qua non* of the implantation of the ovum. The main conclusion was that ovarian pregnancy was a fact, and that it meant pregnancy in a Graafian follicle.

DR. MEYER asked if the preparation had been examined in series of sections through the whole organ: for without that it was impossible to exclude the possibility that the ovum had had its original site on the fimbria ovarica. He also asked if the layer of lutein cells in the wall of the fœtal sac were not interrupted in a limited space where the specimen demonstrated seemed to indicate such an interruption.

DR. PINARD regretted that the speaker had no macroscopical section of the whole specimen showing the relations of the ovary and tube.

DR. VAN TUSSENBROEK replied to Dr. Meyer, that although the layer of lutein cells did not come quite to the opening of perforation, it came very near it. Series of microscopical sections had been made, but not through the whole specimen. As for Dr. Pinard's remarks, although she had no complete macroscopical section, she thought that what was still left of the specimen would prove definitely that the ovisac was quite free from the tube; this she would demonstrate.

**Management of Labor in Abnormal Pelves.**—DR. DAVIS, of Philadelphia, read this paper. He gave the results of his experience in twelve hundred and twenty-four cases, in all of which he had performed palpation and pelvimetry. He adopted as a standard of abnormality a variation from the average of 2 cm. in the antero-posterior diameter, or of 2 cm. in any other two diameters. In every case of suspected abnormal pelvis, it was necessary, with a view to the management of labor, to make a very thorough examination; if necessary under ether. It was of great importance to determine the relations in size of the pelvis and the fœtal head. He emphasized the necessity of examining the excretion of urea. If this fell below one per cent., it was an indication for prompt interference. Eclampsia had not occurred in his cases when they had been under observation before labor; all eclamptics had been emergency cases. The pregnant woman should be got into the best general condition; the emunctories especially should be in order. The speaker then gave some details of practice in the conduct of difficult labor. He usually employed Simpson's forceps with Toulet's device of tapes for axis traction. He found Walcher's position of very decided service when it became necessary to use forceps and the head was not on the pelvic floor. He limited version to cases of simple flat pelvis in which contraction was not great, *i.e.*, the internal conjugate must be at least 8 cm. He did symphyseotomy, with good results, in cases with a true conjugate of 8.5 cm. and upward if the head failed to enter the pelvis. In Cæsarean section he preferred cœliohysterectomy with intrapelvic treatment of the stump. He described his technique. In summing up, he gave the following figures: Thirty-two per cent. of pelves were abnormal. Of these, twenty per cent. required obstetrical operations. The total maternal mortality in abnormal pelves was 1.2 per cent.; total infant mortality, six per cent. He emphasized the absence of infection and of hemorrhage in his cases; also the good results of his Cæsarean sections.

**Nomenclature of the Oblique Diameters of the Pelvis.**—DR. LA TORRE, of Rome, contributed this paper. He called attention to the confusion which existed in the nomenclature of these diameters. Among French and Italian obstetricians the left oblique diameter, for instance, was that one which ran from the left anterior to the right posterior portion of the pelvis; among English, American, and German obstetricians, on the contrary, it ran from the left posterior to the right anterior portion of the pelvis. To the objection that the Germans had now abandoned the terms left and right, and had adopted the terms first and second, he would answer that this denomination rendered only more indeterminate and vague the clinical significance of these diameters. His conviction was that the oblique diameters should be conceived of as running from the ileo-pectineal eminences backward to the sacro-iliac synchondroses; and that they should take their name from the anterior point of departure. His main reason was that, inasmuch as a very large proportion of presentations were vertical, and that in ninety-five per cent. of these the occiput lay anteriorly and to the left, the line of the sagittal suture and the situation of the occiput in this position (anterior and to the left) should (by reason of frequency) give the name to the diameter; which would therefore be called the left oblique diameter. Secondly, in measuring any line, we always intuitively began from the point nearest ourselves. This princi-

ple, applied to the pelvis, would make us conceive of the diameters as running antero-posteriorly. He would, therefore, urge the general adoption of the French and Italian nomenclature, of which he had demonstrated the rationale.

At the conclusion of this paper Dr. Bar proposed that an international committee should be named to consider the question of nomenclature. The following gentlemen were, later, elected as members of this committee: Drs. Treub (president), Bar, La Torre, Rapin, Queirel, de Kein, Davis, Simpson, Freud, and Jue.

The committee immediately nominated Dr. Bar as its secretary, and indicated that the report would be submitted for discussion at the obstetrical session of the Paris Congress in 1900.

**The Morphological Classification of Pelvic Deformities.**—Dr. La Torre, of Rome, presented a second communication having the above title. It was altogether a defence of the classification, based entirely on morphology, which he had devised and presented before the last International Congress of Medicine in Moscow, together with a critique of the various classifications proposed by others since that time. He referred in detail to Müller's classification, to Tibone's, to Fochier's, and to Delore's. All these he rejected in favor of his own, answering at the same time their objections to his.

**Labor and Nephritis.**—Dr. Favre, of Chaux-de-Fond, read a paper with the above title. In following a series of fifteen cases, which he had treated for nephritic affections previous to pregnancy, M. Favre had observed that, while the temperature remained normal during the first two days after accouchement, it ran up to 38° C. and over on the third day; that albuminuria, also, increased gradually to the third day; that at this time they all showed signs of uræmia or pseudo-uræmia—headache, nausea, and visual disturbances. He believed these were certainly uræmic, and had nothing to do with lactation. He believed that the main factors in the etiology of the albuminuria of pregnancy were urinary retention, the frequent presence of bacteria in the blood, the hydræmia of pregnancy, and fatigue. There were two main factors in prognosis: (1) The kind and degree of the fatigue during both pregnancy and labor; (2) the degree of the albuminuria.

**Omphalotripsy.**—Dr. Porak, of Paris, read this paper. He presented an omphalotribe devised by himself. According to clinical experiences detailed, he concluded that omphalotripsy, crushing the cord to the skin level, was the only sure means of preventing infection, and that a dry powder dressing was the quickest way of obtaining desiccation.

The question was then discussed by Drs. Keiffer, Pinard, Chaleix, Queirel, and Bar. The general impression was that the procedure, in view of present aseptic methods, was unnecessary.

**The Action of Quinine in Pregnancy.**—Drs. Chambrelent and Brutère, of Bordeaux, presented this communication. The authors had found a very great variability in the action of the sulphate of quinine. Frequently, even in large doses, it remained altogether without effect in provoking uterine contractions, and even in some cases seemed to arrest contractions already begun. Certainly in some cases it did cause such contractions. Their conclusion was that caution was necessary in administering the drug.

Dr Davis, of Philadelphia, remarked that it was the experience in America that quinine given for malaria in pregnant women did not interrupt pregnancy.

Drs. Cordes, Pasquali, and Pinard also discussed the question, agreeing in the main with the essayist.

**Sections of Frozen Uteri in Pregnancy, Labor, and the Puerperium.**—Dr. Cosentino, of Catania, presented this paper, with illustrative drawings. One case was that of a VIpara at the beginning of the sixth month of pregnancy, who died of cardiac lesions. The second was that of a woman, aged twenty-six years, IIIpara, who had died during labor. The third was that of a girl, aged nineteen years, who died twenty-four hours after a difficult labor, of septicæmia.

**The Influence of Posture on the Form and Dimensions of the Pelvis.**—Dr. Pinzani, of Pisa, who was to have opened the discussion, being absent, his contribution was read by Dr. La Torre, of Rome. Dr. Pinzani first called attention to the fact that, in the movement of the legs from the lithotomy position to that of Walcher, there takes place *pari passu* a movement of the iliac spines, which describe part of a circle in a forward and downward direction, and also a gradually increasing lumbar lordosis; except that the lordosis, after the horizontal position was passed, increased no further. This he proceeded to explain in detail as follows: There was first an increase of pelvic inclination, limited by the tension of the ligamentum longitudinale anterius of the vertebræ and the intervertebral discs. By this tension the sacrum was fixed. The anterior pelvic arch being drawn further downward, the effect would not be perceived for the entire pelvis, but only for the iliac bones, which moved upon the sacrum, describing an arc of a circle forward and downward. The transverse axis for the movement of the iliac bones lay behind the second sacral vertebra. This axis being situated under the promontory, the symphysis must be removed from the promontory by the rotation, while it approached the point of the sacrum; the sagittal diameter of the brim being consequently increased and that of the outlet diminished. This action of the iliac bones was limited partially by the sacro-iliac articulations, partly by the posterior ligament, and somewhat by the muscles of the abdominal wall and by the psoas. He did not need to say that pregnancy would be generally favorable to this dislocation of the iliac bones, but he ought to add that individual conditions may diminish, even in pregnant women, this mobility. Continuing, he gave the results of his own observations. In one hundred and two women, nearly all in the second week after confinement and the others in an advanced state of pregnancy, he had measured with the finger with the utmost exactness the diagonal conjugate in the lithotomy position, in the obstetrical position, and in Walcher's position. By the change of the first position into the third he had found an increase on the average of 7.5 mm.; maximum 17 mm., minimum 2 mm. Between the first and the second position the difference was on the average 1.9 mm.; maximum 5 mm., minimum 0 mm. Between the second and the third position (one hundred and one cases) the average of the increase was 6.1 mm.; maximum 12 mm., minimum 2 mm. The mensuration in the five female cadavers gave smaller differences. Why in the corpse the effect of the change of position was less than in the living he did not know. His researches confirmed the results of Klein, that in contracted pelves the difference between the length of the diagonal conjugata in the obstetrical and in Walcher's position was on the average 8.7 mm., *i.e.*, superior to the general average difference (6.1 mm.). Moreover he found a great variety in the degree of the increase.

The coccypubic diameter would, as he had mentioned, be shortened in a higher degree than the conjugata increased. He did not know whether exact mensurations of this diameter had been made, except those of Küttner. In the five corpses he had examined he found by changing the lithotomy into the obstetrical position, an average diminution of the coccypubic diameter of 5.6 mm., and of 9.2 mm. by changing the

latter position for that of Walcher. The entire difference between the two extreme positions was thus on the average 14.8 mm., and has varied between 26 and 9 mm. He did not need to say that the antero-posterior diameter of the wide part of the excavation did not change, or, if so, very little.

Dr. G. Walcher, of Stuttgart, after reviewing the work on the subject of those before his time, mentioned his own researches, begun in 1885 on dry pelves, in which he found that the antero-posterior diameter of the brim was changeable, as soon as the sacro-iliac articulations allowed however slight a movement. He could not continue his researches until 1889, and then he pursued them in vivo. He started from the idea that it might be possible to obtain an enlargement of the conjugata vera, if the iliac bones could be made to rotate forward and downward. To obtain this rotation he made use of the thighs as a lever. As the ligaments of Bertini prevented an excessive displacement of the femora with regard to the iliac bones, these would be obliged to displace themselves and to rotate as soon as an effort was made to exceed the limit formed by the Bertini ligaments. When the sacrum was fixed, an enlargement of the antero-posterior diameter might be obtained in this way.

As to the practical side of the question, Dr. Walcher arrived at the following conclusions: In moderately contracted pelves there would be scarcely any reason for using the position with hanging thighs, especially when there was a head-presentation and when the uterine contractions were regular. When the woman was allowed to choose for herself the most convenient position, she would herself place her thighs in the most favorable position for the enlargement of the pelvis. When the contractions were insufficient and the head did not enter the brim, the woman might be placed now and then in the position with hanging thighs, and at the same time the head might be pressed into the pelvis according to Hofmeier's suggestion. Above all things it was in obstetrical operations and particularly in applications of the forceps, the head not having passed the brim, and in extraction after podalic version, that the supine position was useful. When the head had not wholly entered the cavity, the woman being in the position with hanging thighs, the femora must be elevated again, while traction on the head was continued, to displace the anterior part of the pelvis upward. Once the head had entered the excavation, the extraction ought to be finished in the obstetrical position. Dr. Walcher appended a complete bibliography of the subject.

Professor Lebedoff and Dr. Bartoszewicz, of St. Petersburg, after noticing the work done by others, notably Walcher, Klein, Küttner, Pinzani, and Varnier, proceeded to contribute in detail the results of their own measurements, carried out on twenty-five female cadavers and two infants. They had used Klein's instrument for measuring. Their conclusions were as follows: (1) In Walcher's position the true conjugate was always greater than in the horizontal position; the difference varied from a fraction of a millimetre up to 3 mm. (2) The true conjugate was shortest in the lithotomy position; the maximum difference in its length in the lithotomy position and in Walcher's was 7 mm.; the minimum 1 mm. (3) The variations in length of the diagonal conjugate corresponded in general to those of the true. (4) A very marked shortening of the true conjugate was observed as soon as, through flexion of the lower extremities, the pelvis was compressed. (5) The coccypubic diameter presented greater variations than the conjugata vera, but in the opposite direction; it was shortest in Walcher's, and longest in the lithotomy position. Minimum difference, 3 mm.; maximum difference, 11 mm.

Drs. Bué, of Lille, and Bonnaire, of Paris, continued the discussion in a joint communication. After a long and careful consideration of the history of the subject and of the figures of previous observers, the authors detailed their own observations and conclusions. They had made very careful measurements on the cadavers of twelve women dead during the puerperium. They had measured especially the antero-posterior diameter of the brim, and the bis-ischiatic diameter, and in the three positions, Walcher's, the horizontal, and the lithotomy. They used in nearly all their measurements the "forced Walcher," *i.e.*, the bodies being in cadaveric rigidity, they overcame this by forcing the hanging lower extremities backward and downward. The pelvis was dissected and the abdomen emptied. They came to the following main conclusions: (1) The attitude of hyperextension of the whole body (Walcher's) had the effect of enlarging the antero-posterior diameter of the brim, both by throwing backward the base of the sacrum, and by forcing the pubis downward. This increase was less than Walcher indicated it to be. It was, on the average, 3–4 mm. (2) The lithotomy position shortened the same diameter. On the other hand, it enlarged considerably the transverse diameter of the outlet. The average increase in the bis-ischiatic diameter, from Walcher's position to the lithotomy one, was 16–18 mm. (3) The hyperextended position (Walcher's) was indicated—(*a*) to allow spontaneous descent of the head; (*b*) to bring about engagement of the head with the aid of forceps; (*c*) to extract the after-coming head retained at a contracted brim. However, the inconvenience of practising obstetrical manœuvres in this position annihilated in practice to some extent the advantages of the slight enlargement of the brim. (4) The lithotomy position afforded a greater enlargement, but was less often indicated than Walcher's. It should be reserved for cases in which the outlet was contracted (kyphotic pelvis); for those in which the head, wedged tight in the true pelvis in a forehead presentation, had to be extracted by forceps; for those, finally, in which, the head being delivered, the shoulders were retained on the pelvic floor by too large a trunk. The lithotomy position favored obstetrical manipulations. The authors finally insisted specially on this point, that in the lithotomy position the greatest increase was obtained when the knees were placed exactly in line with the shoulders, and neither in abduction nor adduction.

Dr. Kouwer, of Utrecht, supported the methods of Walcher, with whose measurements his own agreed.

Dr. La Torre, of Rome, wished to discuss only the point as to whether the posture of hyperextension should bear Walcher's name or not. He thought not, and claimed the honor for Mercurio (1595) and Melli (1721).

Dr. Nijhoff, of Groningen, hailed Walcher's position as a great advance.

Dr. Pestalozza, of Florence, indicated that clinically one seemed often to get by hyperextended position a greater increase of the true conjugate than actual measurements represented. He had found the symphysis to descend 3 cm. Like Drs. Bonnaire and Bué, he had very rarely found an increase of over 5 mm. in the true conjugate.

Dr. Engelmann showed a series of drawings, representing various positions intuitively adopted during difficult accouchement by the American Indians, Asiatics, etc., which showed that the Hängelage was known long ago to ignorant races, although Walcher had now given us a scientific explanation of the reason for its use. He would point out that the true Hängelage used by the Indians (holding on to a hanging rope in the kneeling position, with knees not touching the ground) was advantageous and rational, in that it

allowed constant change of position according to the subjective sensations of the patient.

Dr. Bar gave his own results in mensuration made years ago. He found that the increase obtained by Walcher's position was lost if that position was at all exaggerated so as to increase lordosis.

Dr. Pinard agreed with all Dr. Bué's conclusions, and insisted on the fact that Walcher's position obtained absolutely no enlargement of the pelvis in ten per cent. of cases, and in the rest this enlargement very rarely exceeded 3 mm.

*Fourth Day—Friday, August 11th.*

Dr. Keiffer, of Paris, demonstrated a series of lantern views of microscopical slides, showing the following conditions: (1) The structure of the normal uterus, and especially its vascular system. (2) The development of fibromyomata. These, he thought he had proved, took origin in the walls of arterioles. (3) The uterine mucosa and the successive phases of menstruation. These preparations proved (he considered) that menstruation was in no sense a merely hemorrhagic phenomenon, but a true secretory function peculiar to the uterus.

Drs. Richelot, of Paris, and Reverdin, of Geneva, demonstrated an operating-table, made of steel tubes, very light, and easily transported.

**Total Hysterectomy in Fibromata Complicated by Albuminuria.**—Dr. Delagenière, of Le Mans, read this paper. He would divide cases of albuminuria, with regard to this question, into two classes: (1) True albuminuria, in which the kidneys were intrinsically affected; (2) transitory, in which the albuminuria was caused by compression, some toxæmia, etc., and did not indicate a permanent kidney lesion. He had done this operation in nine cases of this class, with four deaths. Of the nine cases five were suffering from true and four from transitory albuminuria. Now, of the four deaths three belonged to the former class, and only one to the latter. His conclusions were that in true albuminuria hysterectomy was contraindicated; in transitory it was strongly indicated. He emphasized the importance of looking carefully into the history of the case for possible previous Bright's disease, and of examining thoroughly the urine. He considered that fever, malaise, and a considerable amount of albumin indicated probably a toxæmic albuminuria. He reported a case, that of a woman, aged forty years, in whom the fibroma compressed the right ureter. Operation was followed by an immediate good result, and rapid disappearance of the albuminuria.

**Of a Cause of Intestinal Obstruction Special to Fibromata.**—Dr. Gouilloud, of Lyons, said that after removal of a large fibroma, the "statics" of the intestine being suddenly altered, there might result unforeseen adhesions, and acute or subacute obstruction. He reported two illustrative cases. In one a fibroma weighing 8 kgm. was removed by enucleation; ten days later at a second operation the small intestine was found adherent to the area of enucleation and obstructed. In the second the sigmoid flexure was obstructed, its mesocolon having been drawn down by the suture in closing the pelvic peritoneum of the first operation (hysterectomy) into Douglas' pouch.

**Surgical Treatment of Fibromyomata.**—Dr. B. Jessett, of London, read this paper. After reviewing shortly the history of the subject, he went on to consider the operative indications. He classified fibromata as subserous, intramural, submucous, combined subserous and intramural, polypoid, those becoming malignant, and those complicated by pregnancy. Small quiescent tumors he would leave alone. Subserous should be treated by laparotomy to permit inspection. Enucleation was necessary for single ones or for very few; pan-hysterectomy for multiple fibromata, except when the patient was in poor condition, then a subperitoneal operation should be done. In submucous and polypoid growths, the vaginal enucleation was necessary.

Dr. Gordon, of Portland, discussed the indications for operation. If a woman with a fibroma came to him, and after examination he believed her symptoms to be due to the fibroma, he advised operation, even though the tumor was small. He believed in the vaginal route for submucous fibroids, but for all others the abdominal. And if he could not do a vaginal operation, he believed hysterectomy was the only alternative, with two exceptions: (1) in the case of a pedunculated subserous tumor; (2) in the case of a woman in the child-bearing age. In these myomectomy might be done. But he considered myomectomy bad surgery in any woman past the child-bearing age, because of the likelihood of other fibroids developing later. Very few women with fibroids became pregnant anyway. In hysterectomy those who had borne children and had lacerations should have the total operation done; in the others he would leave the cervix. In conclusion, he said that he denied the assertion that myomectomy was conservative surgery. Conservative surgery should conserve health; and myomectomy failed to do that.

**The Pathogenesis of Cancer.**—Dr. Robert Bell, of Glasgow, presented a communication with this title. The author mentioned the ovum as an example of a cell leaving one organ and proceeding to another, where it took on a new and rapid growth, and entered on a new phase of existence by virtue of its environment. If the transmigration of one cell could take place, it might occur in other than physiological circumstances. Indeed, he said, it frequently was observed pathologically when glands became involved in disease which had previously existed in a neighboring or even a comparatively distant tissue. Why, then, should not the same rule apply to cells having at the moment no pathological or even pathogenic significance? He remarked that if a cell possessing in its original environment an activity normally high found its way into an organ which for some cause or other has had its health—it may be only temporarily—depressed, the invading cell became enabled to enter on a new phase of existence, and by preying upon its host to develop a progeny which possessed quite different proclivities from those they would have possessed had they been the offspring of their parent cell had it continued in its normal sphere of existence. It had been placed beyond doubt that the ovaries and mammæ were in communication through the lymphatics, and the author was inclined to suppose that an ovarian cell was thus enabled to find its way to the mamma and there become the focus of scirrhus. He was quite at variance with those writers who supposed that cancer was due to a parasitic entity which in any way was developed external to the economy. He then endeavored to show how epithelial cells might, and in all probability did, depart from their normal condition in certain circumstances and in their transition became malignant, and how this untoward result might be avoided, and when it had actually occurred be undone. The speaker then pointed out that in carcinoma of the cervix frequent mistakes were made in diagnosis, and in many instances when no cancer existed an unnecessarily pessimistic view was taken.

**The Principles of Treatment in Uterine Fibromata.**—Dr. Woskresensky, of Kieff, read this paper. He based his conclusions on an experience of three hundred cases, of which one-half had been operated upon by him and one-half had not. He believed that the size of the tumor gave no constant indications as to

the principles of treatment. He noticed the frequent bad influence of fibromata on the general organism. Cachexia often developed before malignant degeneration could be diagnosed. He formulated the following conclusions: (1) Fibroma of the uterus was an element of danger to the organism. (2) Radical treatment could be only operative. (3) The operation should be done early, before the patient showed signs of enfeeblement. (4) Total hysterectomy was necessary in fibroma of the body. (5) The ovaries should not be removed, except when special indications therefor existed. (6) Ergotin hypodermically was worse than useless. (7) Pregnancy was no contraindication to operation. (8) Total hysterectomy was preferable to leaving the cervix, because of possibility of recurrence or development of cancer in the latter.

**Large Uterine Fibromata, with Torsion of the Pedicle in One; Total Abdomino-Vaginal Hysterectomy; Technique.**—Dr. d'Hotman de Villiers, of Paris, described the case of a woman, aged thirty-four years, who suffered from acute symptoms caused by the torsion of the pedicle of a fibroma, simulating at first a salpingitis. There were present also two other very large fibromata, the whole weighing 5.5 kgm. He had performed total abdomino-vaginal hysterectomy according to Lebec's method, but with certain modifications of his own. These were as follows: After freeing the bladder he opened first the anterior cul-de-sac, and through this passed a silk ligature into the vagina; then on through the posterior cul-de-sac back into the abdomen. This ligature thus formed a loop in which was comprised the base of the broad ligament and the uterine vessels. This he tied near the cervix, and then cut free on that side. This he repeated on the other side, and so removed the whole mass without trace of hemorrhage. He did not close the peritoneum, but drained through the vagina. He had done this operation eight times, with one death from pneumonia; and had had good results. In the last three cases he had used in addition Doyen's angiotribe. He reserved the operation for large and adherent fibromata.

**Of Special Operations in the Treatment of Uterine Fibromata.**—Dr. Duret, of Lille, referred especially to two operations devised by himself: (1) Autoplastic operation on the pelvic serosa; (2) abdominal morcellement of fibromata and of sessile cystic fibromata. The indications for the latter were: very dense adhesion of the uterus to the pelvic walls and surrounding organs; calcified fibromata; cystic fibromata. The first operation was devised to cover in the pelvic floor with peritoneum in cases in which the removal of very large fibromata had left a vast denuded area, extending over the rectum, uterus, and bladder. It consisted in simply suturing the anterior parietal layer to the end of the posterior parietal layer at the promontory, after loosening it up if necessary.

**On the Treatment of Fibromata during Pregnancy.**—Dr. Doléris, of Paris, read a paper with the above title. He based his remarks on an experience of ten cases. There was a certain class of cases in which he would advise active interference, viz., those in which the fibroid took on rapid growth, becoming even cystic. These were apt to be the starting-point of a grave septicæmic course, and the prognosis was distinctly bad. He did not advise interference if the fibroid was situated on the fundus or the cervix, and was unlikely to cause dystocia.

Dr. Gutierrez, of Madrid, had never met with fibromata requiring interference during pregnancy. He believed it was best to wait till the beginning of labor, or near term, and then, if necessary, do Cæsarean section. This he had done twice.

Dr. Engström, of Helsingfors, related the details of five cases. In one he had removed at the fifth month a large myoma, and two months later twins were born. Later the woman became pregnant again and had a normal labor at term. Three others were of a similar nature—the women were operated on, and bore children later. In the fifth case he had operated for peritonitis; the patient died. He had seen many others which he had not operated on.

Dr. La Torre, of Rome, objected to Dr. Doléris' advice to remove the uterus with the fibroma in pregnancy. If the volume of the fibroma did not prevent the progress of the pregnancy to term, he believed it was wrong to remove the uterus immediately. One could afford to wait until term. It was only right to extirpate by Cæsarean section, and then only at the last moment.

Dr. Solovieff, of St. Petersburg, thought also that it was best to wait till term.

**Surgical Treatment of Fibromyomata.**—Dr. Gutierrez, of Madrid, read this paper. He would make a threefold classification of fibromata in regard to operation: (1) Operations of urgency—*e.g.*, made necessary by extreme anæmia, obstruction, hemorrhage. (2) Operations of absolute necessity—*e.g.*, fibromata of rapid development, or accompanied by too abundant hemorrhage. (3) Operations of relative necessity—fibromata which do not necessitate cessation of work. As to technique, he approved of Doyen's anterior hemisection method in difficult cases. He was against the vaginal route for large fibromata. If the tumor exceeded one finger's breadth above the pubis he would advise the abdominal route. He preferred the total operation. Myomectomy he reserved for subserous pediculated tumors.

**Statistics of Operations for Fibromyomata during the Last Three Years.**—Dr. Treub, of Amsterdam, read this paper. For fibromata of medium size and of soft consistency, causing no symptoms beyond hemorrhage, the speaker usually began with injections of ergotin or electricity. He had seen thus both radical and symptomatic cures. His statistics embraced 76 cases: Myomectomy by abdominal route, 11 cases; by vaginal route, 2 cases. By the abdominal route 1 death occurred from infection. He favored more and more enucleation by the abdominal route. Total myoma-hysterectomy by abdominal route, 9 cases, of which 3 were fatal (1 from operative infection); by vaginal route, 23 cases, of which 5 were fatal (2 from infection by the operation and 1 from intestinal obstruction). He declared himself in favor of this operation, and remarked that soft fibromata rendered morcellement difficult, and that hemorrhage was not always unimportant. Supravaginal amputation, 31 cases, with 3 deaths (1 from infection by operation). He believed in the buried elastic ligature. He would reserve total hysterectomy for exceptional cases.

**New Procedure in Abdominal Hysterectomy.**—Dr. Schmeltz, of Nice, presented a communication on this subject. The main point of this operation consisted in the use of the "angioclast," an instrument devised and named by himself, and which had the advantage over the angiotribes of Tuffier and Doyen of being much more easily handled and of crushing by the mere pressure of the hand. An antero-posterior buttonhole incision was made through the cervix into Douglas' pouch. One branch of the angioclast was passed through this, and the other on the outside of the cervix. Thus each lateral half of the cervix was in turn crushed. He applied no subsequent ligature. The operation was completed as an ordinary supravaginal amputation. This method of hæmostasis shortened the operation very greatly.

**The Surgical Treatment of Fibromyoma of the Uterus.**—Dr. Schauta, of Vienna, opened the discussion with an account of the results of his personal experience founded on 424 cases of operative treatment

of myoma uteri with opening of the peritoneum, in a series of 2,263 cœliotomies performed by himself. He discussed in detail most of the typical operations, and gave in each his own statistics: In 148 cases of vaginal total extirpation he had 5 deaths (of which 2 could not be considered as due to the operation); in 25 myomectomies by laparotomy he had 5 deaths (of which 3 were from embolism and pneumonia). Supravaginal amputation, with intraperitoneal treatment of the pedicle, he had done only 3 times, with 2 deaths. Of 106 cases of abdominal total extirpation he had 12 deaths, of which 2 were not due to the operation; giving, therefore, a mortality of 9.4 per cent.. He then described his technique for the last-mentioned operation. His conclusions were as follows:

1. Operative treatment for fibroid tumors was not legitimate except when they were the cause of troubles that were not to be overcome by other means.

2. Vaginal total extirpation should be considered as the safest and, in the long run, most successful operation. It should be performed in all cases when the tumor did not extend above the level of the umbilicus, and when it could be easily drawn into the small pelvis.

3. For large, not easily movable tumors, wholly or partially intraligamentous, abdominal total extirpation should have the preference.

4. Supravaginal amputation with intraperitoneal treatment of the stump should be gradually set aside in favor of abdominal total extirpation, although the immediate results of the former were more favorable: it had been proved that there were more chances for absolute recovery when no part of the cervix was allowed to remain.

5. In emergency cases, supravaginal amputation with extraperitoneal treatment of the stump was, as it afforded facility for speedy and absolutely extraperitoneal execution, an advantage not to be underrated, in cases of extreme anæmia, asphyxia, weakness of the heart, and suppuration or necrosis of the tumor.

6. Vaginal enucleation of sessile, submucous tumors, either by way of the dilated cervix or by the vaginal fornix, after anterior or posterior colpotomy, with or without opening of the peritoneum, should be resorted to only in cases in which there were special indications. Myomata being generally multiple, it would not be likely that the operation would afford durable results, and therefore it could not be considered as less dangerous than the radical operation, with removal of the uterus.

7. Curettage should be looked upon as an uncertain mode of treatment, was not wholly free from danger, and should be limited to rare cases of beginning myomatous development.

8. Castration should be strictly objected to on the ground of its not bearing comparison with the radical operations, with regard to reliability and immunity from danger. In quite exceptional cases, when it was not possible to perform supravaginal amputation with extraperitoneal treatment of the stump, it might now and then be resorted to.

9. It was not to be thought that the methodical use of forcipressure (pinces à demeure) afforded the patient advantages superseding the use of ligatures, except in so far as they facilitated a speedy operation in typical cases. In cases of emergency or danger their use was certainly to be justified. He had had seven deaths in forty cases, mainly from secondary hemorrhage after removal of clamps.

10. The full value of drainage of the supravaginal wound for furthering throughout the chances of asepsis, and for the avoidance of exudation, in abdominal as well as in vaginal total extirpation, should be always kept in mind.

11. The question as to whether removal of the ovaries should be performed, with vaginal or abdominal total extirpation, was not yet decided. "Ausfallerscheinungen" (climacteric symptoms) had been observed either way. If the ovaries were removed these appeared immediately; if they were left, after weeks and sometimes months.

Dr. Doyen, of Paris, presented a most exhaustive report upon the subject under discussion, occupying thirty-five printed pages. Of this only a short abstract can be given. He began by justifying a more extensive practice of surgical interference, inasmuch as grave complications of fibromata not infrequently occurred, viz., phlebitis, albuminuria, intestinal obstruction, malignant degeneration. Palliative measures, so called, should be altogether discredited. He would endeavor to show that his method of vaginal hysterectomy without preliminary hæmostasis, by anterior hemisection, together with that of total abdominal hysterectomy by subperitoneal decortication of the inferior segment of the uterus, constituted the two greatest advances of late years in the surgery of fibromyomata (1887–92). He would claim for his own technique in these operations that it was so simple as to be incapable of any notable improvement, so safe as to suppress almost entirely the risks of operation; that it was suitable, with slight modifications of detail, to all cases without exception; and that it was within the reach of all surgeons. He then discussed at length the history of operations for fibroma, from the vaginal myomectomy with conservation of the uterus, of Amussat (1840), down to his own procedure, published first in 1887. Since 1892 he had changed the technique of his hysterectomy operations only in one or two details, viz.: In the vaginal operation, the substitution of momentary angiotripsy followed by ligature *en masse* of the broad ligaments for the old pinces à demeure; in the abdominal operation, the adoption of Trendelenburg's position, the suppression of pinces à demeure in favor of angiotripsy, and the isolated ligature of the uterine arteries and the stumps of the adnexa.

Dr. Doyen then proceeded to discuss the indications for operation. His conclusions were as follows:

1. Fibromata should be removed in all cases in which they caused serious symptoms, or in which they increased steadily in size.

2. Albuminuria, as a complication, was a very decided indication for operation.

3. Operative technique should be, in these days, fixed as definitely as that of an amputation of the thigh.

4. Myomectomy, either by the vaginal or abdominal route, the uterus being left, was now but rarely indicated.

5. Multiple myomata required hysterectomy.

6. Hysterectomy should be done by the vagina when the uterus was mobile and could be easily pulled into the pelvis.

7. A large vagina (previous pregnancies) was an indication for the vaginal route; the same might be said of obesity, in the case of small tumors, as a fat abdomen rendered a laparotomy very difficult.

8. The abdominal route should be chosen in all cases in which it appeared more favorable than the vaginal. In cases in which the uterus approached the umbilicus, the experience of the individual surgeon counted for a great deal. Among definite indications for laparotomy were old adhesions, hydro- or pyo-salpinx, the presence of large tumors of the adnexa. When there was any doubt as to the practicability of the vaginal operation, it was better to choose the abdominal.

Dr. Doyen then gave exact details of his operative technique for all varieties of fibroma and for all the routes he practised. His statistics, since perfecting his technique, showed forty-two vaginal hysterectomies without a death, and twenty-five abdominal with one

death; this was of a woman who had an infectious phlebitis of the lower extremities before operation.

Dr. Baldy sketched the history of the subject. Since 1853 (Burnham, Kimball) there had been three periods. In the third, in which we now were, the great question was the relative merits of myomectomy and hysterectomy. He dismissed in a few words all other operations. In his opinion, hysterectomy was the operation of choice. Myomectomy did not cure with certainty; pain in many cases persisted; bleeding, depending as it did principally on situation rather than size, frequently continued; there was danger of recurrence (Kelly, the great advocate of myomectomy in America, had had three known recurrences in ninety cases, and probably many others unknown). The operation, moreover, was more dangerous than hysterectomy; and the dangers of hemorrhage and sepsis were greater. Adopting, then, hysterectomy as a general thing, he preferred usually the abdominal route. In the vaginal operation there was no chance of revising the diagnosis; the operation field was limited; morcellement was frequently necessary; the possibility of treating complications or accidental injuries to the hollow viscera was minimal. In the abdominal operation he preferred the operation at the neck. It was a shorter operation; it was applicable to all cases; it necessitated less handling; it opened up less connective-tissue spaces and inflicted less trauma; it was less liable to infection; the anatomical relations of the vaginal vault were retained, and the vagina was not shortened; the floor was more easily re-covered with peritoneum than when the cervix was removed. In hæmostasis, ligature was the only sure method. Forcipressure and cauterization were still on their trial. In conclusion, his position was directly in opposition to that of Schauta.

Dr. Delagenière, of Le Mans, claimed that the palliative method of tying the uterine arteries by the vagina had a definite place. He had done this five times since 1896 with uniformly good results. He thought it was indicated in (1) small interstitial fibroma; (2) multiple fibromata; (3) cases in which more radical operations were refused, and in which the main symptom was hemorrhage.

Dr. Reynier, of Paris, agreed with Schauta that every fibroma should not be operated. Still, fibromata were very often far from benign; their evolution was dangerous; a young woman benefited more from interference, provided this was not dangerous, than from being left alone; operations were becoming more and more innocuous, especially in the young, while they remained more or less dangerous for the old. For all these reasons he was becoming more and more a partisan of early operation. Dr. Reynier then presented his own statistics based on 111 operations: 53 vaginal hysterectomies and 58 laparotomies, nearly all hysterectomies. He described his own technique for abdominal hysterectomy and concluded as follows: Vaginal hysterectomy was the operation of choice in cases in which the uterus was not larger than a fœtal head, when the uterine cervix was not obliterated, and there was a dilatable vulvo-vaginal outlet. Abdominal hysterectomy should be done in cases in which the size of the uterus was greater than a fœtal head. For this operation one should be familiar with several different techniques, and should employ each according to indications.

Dr. Tuholski, of St. Louis, agreed on the whole with Dr. Baldy's remarks, but was not so radical. The supravaginal amputation was his preference; but if the cervix contained fibroids he did a total operation. He would still treat the stump extraperitoneally when time was of great consequence. He based his remarks on an experience of one thousand laparotomies.

Dr. Alexander, of Liverpool, said that the object of gynæcological surgery, in his opinion, was to remove the disease without destroying any organ. This principle had been slighted in the operations just advocated. He believed myomectomy was the operation of the future. The fibroid caused the symptoms; therefore it was rational to remove the fibroid only. It was unjustifiable to remove the uterus in young women. He had done twenty-three myomectomies, in one case removing twenty-five tumors, without a death and without recurrence of symptoms. Recurrence of the tumor often did not necessitate operation. In Dr. Kelly's statistics three out of ninety had needed a second operation. Even so, the preservation of the uterus in the other eighty-seven more than overbalanced the necessity of a second operation.

Dr. Carstens, of Detroit, agreed altogether with Dr. Alexander. He had made it a rule to be guided by the age of the patient. In a young woman, sterile, he advised myomectomy; in one near or beyond the menopause, hysterectomy; in the latter, if a virgin, a supravaginal; if a multipara (with lacerations which might induce malignant disease), a total operation.

Dr. Bell, of Glasgow, after discussing the pathogenesis of fibroids (which he considered to lie in the organization of a blood-clot), said that in operative treatment he preferred supravaginal amputation, but considered that, in most cases, mammary gland by the mouth should be tried for a considerable period before operation; this had frequently given good results.

Dr. Jacobs, of Brussels, would operate all fibromata, except small nodules without symptoms and remaining stationary. The operation of choice was total hysterectomy, except in the virgin, when it was the supravaginal operation. Contraindications were extreme anæmia, intrinsic albuminuria, degenerated tumors with grave visceral complications, cancer of the cervix—in a word, all cases left until too late. Early operation was necessary while the patient was in good condition. His personal statistics were as follows: Abdominal hysterectomy in 133 cases gave three per cent. mortality; vaginal, 3.7 per cent. mortality.

Dr. Giles, of London, thought that all cases which gave trouble should be operated. Ergotin and electricity were worse than useless. The total hysterectomy was preferable as a usual thing; myomectomy and the supravaginal only in special indications. The ovaries should be preserved.

Dr. Engström, of Helsingfors, preferred abdominal myomectomy; he presented statistics of 180 myomectomies (1888–99) with a mortality of not quite three per cent. He had never seen cancer arise after this operation, and recurrence had been rare and had not necessitated operation. He knew of nine of his patients who had later become pregnant, of whom one had previously been long sterile. Of these, five came to term and four aborted.

Dr. Jonnesco, of Bucharest, gave a long critique of Dr. Doyen's conclusions, disagreeing with several. We should operate early, not for "alarming symptoms" only. He thought the presence of a fibroid was sufficient operative indication. The abandonment of the combined operation was the greatest step in advance of late years. He believed in total hysterectomy in most cases; a partial operation, in his experience, was frequently followed by recurrences. He rejected the statement that Doyen's technique was the simplest and the best. Others were as good; and we must be eclectic and choose the operation suited to each case.

Dr. Jessett, of London, said that myomectomy was rarely indicated. Total hysterectomy should be done for multiple fibromata and in those cases past the menopause; otherwise, the supravaginal operation is indicated. The ovaries should be left.

Heywood Smith, of London, said that fibroma was a dangerous disease, and should be operated upon when it caused the least symptoms. He preferred the subperitoneal to the pan-hysterectomy operation because of its rapidity.

Dr. Henricius, of Helsingfors, had long operated by Chrobak's retroperitoneal method, which gave him three per cent. mortality.

Dr. Sinclair, of Manchester, protested against the tendency to hurry operation. The likelihood of a malignant degeneration was no greater than that of disappearance of the tumor. Enucleation in the fleshy myoma was very dangerous or impossible. He believed strongly in the vaginal route when possible. He emphasized the importance of leaving the ovary.

Dr. Jayle, of Paris, emphasized the train of mental and nervous symptoms following removal of the ovaries, and strongly urged leaving them.

Drs. La Torre of Rome, Galvani of Athens, Tourney of Paris, Villar of Bordeaux, and Pestalozza of Rome also took a short part in the discussion.

At 5 P.M. Dr. Doven, of Paris, gave a second series of cinematographic views, representing two abdominal and three vaginal hysterectomies, according to his own method. He also showed views of his operating-table and of his armamentarium for the performance of hysterectomy. As before, the rapidity of operation was the salient point. The images were extremely clear, and each step of the operations could be followed.

## Correspondence.

### OUR LONDON LETTER.

(From our Special Correspondent.)

EXIT THE HEAT-WAVE—HOSPITAL-ABUSE CORRESPONDENCE IN "THE TIMES"—SANITARY CONGRESS—A STRIKE OF SURGEONS—OYSTERS AND COCKLES—DEATHS OF PROFESSOR CUMING AND F. E. HICKS.

London, September 1, 1899.

The heat wave I wrote about in my last has passed away and we have had several days of broken weather; in some places showers, in others heavy downpour and thunder. The farmers are rejoicing and hoping for more, as the long drought has dried up the ground to a great depth. This also affects the rivers, as the water is absorbed before reaching them. The threatened scarcity of water is therefore not yet removed. On the other hand, the hop crops are injured by the heavy rains, and the pickers are suffering from exposure and want of work.

The correspondence in *The Times* on hospital abuses has gone on merrily enough. Mr. Loch, secretary of the Charity Organization Society, pronounced the inquiry system, as at present carried on, to be only a sham—a term which many attribute to his society. Sir Trevor Lawrence, treasurer of St. Bartholomew's Hospital, took up the cudgels for hospital managers, and declared that to make it a reality would be a waste of money and time, fortifying himself with the small amount of abuse discovered at his hospital, where in the last five years seven hundred and sixty thousand applicants have been treated. A discussion in *The Times* even in this dull season cannot fail to do good by directing public attention to the subject.

The Sanitary Congress met at Southampton on Tuesday, when Sir William Preece delivered his presidential address. He declared that we moderns might study with advantage the wisdom of Moses as to sanitation, and he had no doubt that Moses would have approved of our modern dust destroyers, for he despised dust and endeavored to render it harmless. The book of Leviticus he described as "a treatise on hygiene by the greatest sanitary engineer the world has ever known." The teaching of Moses comprised pure air, pure water, pure food, pure soil, pure dwelling, and pure bodies. These are the sanitary requirements of to-day. Sir William looked forward to the time when electricity would give us pure air, pure water, and help us in the treatment of sewage; while aided by sanitary science the war against microbes would be so successful that human life would undoubtedly be prolonged beyond the psalmist's allotted term.

The president deprecated the plan of casting our sewage into the sea, and thought if the bacterial treatment of sewage enabled us to get rid of sewage farms, it would be a most beneficial advance. He advocated the use of sea-water in towns for various purposes.

At the luncheon of the Institute, Mr. H. Law, chairman of the committee, said they had held seventeen hundred examinations, granted thirty-two hundred certificates, and were about to begin other examinations in hygiene, one for meat inspectors and another for school teachers. The exhibitions they had held had been visited by three-quarters of a million of people. In the evening the mayor of Southampton opened this year's exhibition, which is quite equal to its predecessors.

A strike of surgeons has actually taken place in the colliery districts, which affects some hundred surgeons and from two to three thousand miners. It seems that one of the miners' clubs refused to listen to the representations of the Colliery Surgeons' Association recently established, and advertised for medical men to come into their district. One man has done so, and of course will not be recognized by the colliery surgeons, and if he is wise will withdraw from a position which must become untenable, for the other surgeons are absolutely unanimous and will under no circumstances recognize the intruder. Moreover, they decline to attend any member of the Wigan Society, which has treated them so badly. The club is governed by a board, and the quarrel is really with that board rather than with the members. Each member of that board draws 5*s.* and travelling expenses for attending a meeting, more than in many cases a surgeon receives for attending an accident case, whatever number of visits may be required. In one district the amount paid for accident cases was only 1*s.* 2*d.*, in another 2*s.* 4½*d.* per case. The surgeons offer to attend accidents for 15*s.* per case, this fee to cover attendance for twelve months if necessary. They have offered to meet the miners themselves at the general meetings, but the board will not hear of this. It is believed that the men themselves, if the matter could be properly explained to them, would be quite ready to meet the surgeons, whom they have long been accustomed to trust, but their board seems determined to fight the matter out. There is therefore no resource but to meet the board with their own trades-union weapons. This the Colliery Surgeons' Association has been driven to, and it is probable they will succeed.

As the oyster season opens to-day many are recalling the cases of typhoid which have been traced to the bivalve. The report of the local government board enumerates those oyster beds which are free from suspicion of pollution, and some of the newspapers advise consumers to insist on a guarantee that their purchases are obtained from clean beds. Some of them are good enough to say that medical men will be happy to tell them which are the clean beds, and thus another burden is laid upon us, for of course such advice will be expected to be gratuitous, and we must arm ourselves with the local government report.

But the oyster is not the only dangerous shell-fish. An outbreak of typhoid has been traced to the consumption of raw cockles gathered from mud-flats near a sewerage outlet at Ermouth. Cockles are mostly eaten cooked, but every now and then trippers to the seaside may be seen eating them raw, evidently a very dangerous proceeding.

Dr. James Cuming, of Belfast, died rather suddenly on Monday from disease of the heart, in his sixty-ninth year. He was professor of medicine at the Queen's College for some thirty-four years, and enjoyed a consulting practice throughout the province, his opinion being valued and his character respected by all his professional brethren. In 1884 he was president of the British Medical Association, when his personality contributed largely to the success of the memorable Belfast meeting. He had intended to be present on Sir Thomas Lipton's yacht with Lord Russell at the coming America cup race, his daughter being married to the Hon. Charles Russell.

Francis Edward Hicks died on the 14th ult. in his ninetieth year, being one of the oldest members of the College of Surgeons, his diploma dating 1832. He practised for upward of thirty years in the Cavendish Square district, and retired in 1876. He succeeded his father, the late Samuel Hicks, who died at the ripe age of ninety-four years.

## "OVERCROWDED PROFESSIONS."

To the Editor of the Medical Record.

Sir: A friend has lent me your paper of September 2d, with its leader on "Overcrowded Professions." You have my sympathy in your professional congestion, but I doubt if it is as bad as that of the parsonic order. Can you tell me if your medical schools offer everywhere to every college graduate of decent morals a free training with all needful expenses paid, so that he may attain professional life entirely at the expense of the charitable? I do not think the doctors are quite so foolish, and it is this barbarity I protest against with all my heart.

In your comments on my letter you speak of the self-delusion of the young man who feels sure of personal success where others fail, and in the very admirable paper on "Suggestion," by Dr. H. H. Seelye, I catch a glimpse of a possible cure. Could not every aspirant for professional life be treated by suggestion? It might be hinted to them that the chances are about one hundred thousand to one against their having genius; that while very good, they are but ordinary commonplace young men after all, and could serve their generation better by planting potatoes and raising pork than by trying to doctor the souls, bodies, or estates of men. It might work a cure, though when vanity is allied to physical indolence recovery is doubtful.

But you are better off, after all, than the ministers. To succeed in your profession a man must have both knowledge and skill. I see with pleasure some friends of mine getting on in the world, but they deserve it—they are good doctors. But what do you think of the standard of judgment that makes the following possible? and it it is not an isolated case, but a symptom. I asked a friend about a young clergyman, settled a year or more in a somewhat important parish: "How is Mr. Blank doing?" "Oh," was the answer, "he is exceedingly popular. Certainly, he is a very poor preacher, but he is a most delightful society man." Your advantage is that most folk care more for their bodies than they do for their souls, for a man might have the manners of a Lord Chesterfield, but if he did not know a mint julep from a dose of Epsom salts no sensible person would allow him to play tricks with their stomachs. But then headaches are a present annoyance, while moral weakness has few pathological symptoms; and if a preacher is gifted with insight and honesty and tries very hard to cure the real troubles in the body politic, the chances are that some person, who suffers from an abnormal moral malady and makes a sordid profit out of it through the folly of others, will make such outcry against him that to save his life he must leave the whole parish to itself. Skill in my profession does not insure success, but in yours it will, unless handicapped by bad habits.

My remedy for the overcrowded ministry is to place the theological student upon his feet and let him work for his profession like a man, as you make your students, and you get men after all. We turn out by our system a mucilaginous assortment of incompetents, that fail to win the manhood of the nation to the church. And were it not for the few brilliant exceptions that command respect, the church would be in a worse way than it is to-day.

Magee Pratt.

Hartford, Conn., September 11, 1899.

To the Editor of the Medical Record.

Sir: In the article "Overcrowded Professions" in a recent number of the Medical Record, the writer endeavors to comfort the physician by stating that his condition is equal to that of the clergyman, a statement which conveys the idea that the writer actually believes the two professions can be compared to each other, and that the poor condition of their members is due to the same cause. I take the liberty to assert that the medical and clerical professions can by no means be compared. When the latter is overcrowded, we must not forget that it is overcrowded by professionals, clergymen, men who worked hard till they obtained their degree and title, and a person without theological education will never venture to fulfil the duty of a clergyman.

But what of the medical profession? If the latter were overcrowded with physicians only, the profession would flourish. But to our regret we see that it is overcrowded, not by professionals, but by ignorant creatures who harm not only the income of the physician, but also his reputation. I need only mention the great number of ignorant midwives who endanger the physician's bread, and what more, the patient's life! How many cases of puerperal sepsis occur through the midwife's ignorance, how many perineal lacerations occur that are either not recognized or ignored by the midwife, and the woman remains crippled till she is compelled to undergo a painful and dangerous operation, a thing that could be avoided by a skilful physician. It is true that a great number of women are too modest to be confined by a male physician. But have we not women physicians that are as skilful as their male colleagues?

Next come the so-called "Christian Scientists," who make use of the people's ignorance. We have all heard of the many deaths attributed to these "healers," yet there are thousands of superstitious people, who, being afflicted with grave diseases, would rather go to a Christian Scientist or spiritualist than to submit even to the most skilful physician.

Lastly I will mention the number of druggists who dispense medicines without a physician's prescription. If these invaders of the profession were legally repressed, if a law was passed and energetically executed that medicine, surgery, and midwifery should be practised by physicians only, no matter how the number of physicians might increase none of them would have cause to complain, and the profession would be one of the most flourishing in existence.

M. Gottesman, M.D.

77 Ludlow Street, New York City.

# Medical Items.

**Contagious Diseases—Weekly Statement.**—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending September 16, 1899:

| | Cases. | Deaths. |
|---|---|---|
| Tuberculosis | 131 | 117 |
| Typhoid fever | 99 | 16 |
| Scarlet fever | 63 | 4 |
| Measles | 41 | 6 |
| Diphtheria | 148 | 15 |
| Laryngeal diphtheria (croup) | 4 | 10 |
| Cerebro-spinal meningitis | 0 | 3 |
| Chicken-pox | 4 | 0 |

**Ice-Cream and Micro-Organisms.**—Dr. Reginald Duffield, medical officer of health for Paddington, London, in his report to the local vestry for the past year, states that a bacteriological examination of ice-cream sold by street venders and in shops demonstrates two facts: (1) That the compound sold by the street venders, being made by boiling the ingredients previous to freezing, contained as a rule fewer micro-organisms than that sold by the better-class manufacturers, who make their cream ices from cream and fruit, not from custard; and (2) that the premises occupied by the street venders required supervision to insure that the ices were not exposed to exhalations from drains, etc.

**The Difficulty of Procuring Skilled Teachers for the Deaf.**—A British weekly speaks as follows on the above subject: "In the report on schools for the blind and deaf some curious facts appear. In one very small school-board district the expense of educating one deaf child trebled the school rate. There is a remarkable difference in the cost of educating the blind and the deaf. The former is comparatively easy; the latter requires teachers of exceptional skill. To give language is one of the most difficult tasks, but with the opportunity of a steady course of prolonged training extending over some eight years, it is successful, and association with others becomes possible. In compensation, while the maintenance of the blind requires throughout life some support from society, the education of the deaf renders them independent. Difference of ability, too, requires taking into consideration, and the London school board are preparing to execute a very hopeful plan for establishing a small institution for the defective deaf who cannot be educated with other deaf children of ordinary intelligence. Another difficulty is the dearth of trained teachers, especially men. The prospects are not attractive pecuniarily, and yet men are more required on account of the physical strength and endurance required and a perseverance through a long course of years which cannot be expected of women. It is estimated that there are in England and Wales about thirty-two hundred deaf children, probably an underestimate."

**A Patent-Medicine Firm Come to Grief.**—A man and his wife recently made an agreement with their family physician to make and sell under their name an alleged remedy for malaria, the prescription for which was furnished by the physician. It was a profitable arrangement to all parties until the man and wife quarrelled and went to law, when the scheme was made public, much to the physician's disgust probably.

**Sleeplessness from Overwork,** and especially literary work, requires mental rest and change of air and scene. Temporary exposure to the cool air of the bedroom or the wet pack, or both, may be of use, and so is a glass of whiskey and water at bedtime, especially in those unaccustomed to the use of alcohol. But if the insomnia continue it is necessary to give a mild hypnotic such as twenty grains of sulphonal or thirty or forty grains of bromide of potassium to break the habit of sleeplessness. Capsules containing thirty minims of turpentine given at bedtime are sometimes beneficial in the insomnia of overwork and worry. The drug acts as a stimulant and derivative, and is stated to be most successful in plethoric cases. No beverages containing caffeine should be taken after breakfast.—Bradbury.

**Overcrowding in London.**—According to a tabulated statement, there are in the parish of St. Mary's, Newington, 4,057 tenements with one room, 7,670 with two rooms, 1,752 with three rooms, and 331 with four rooms, which are overcrowded; altogether 13,810 tenements out of a total of 49,393. These are estimated to contain 15,150 overcrowded persons in tenements of one room, 40,184 in those of two rooms, 13,742 in those of three rooms, and 3,580 in those of four rooms, or altogether 72,656 people.—*Sanitary Record.*

**The Course of the Plague in England.**—In England the plague generally showed itself in London in June or in July, though sometimes earlier, and increased in intensity until August. It gradually died away in November and December, the cold of England taking the place of the heat of a more southern country in temporarily destroying the pestilence. This was the course in the sixteenth and seventeenth centuries, and if the disease comes here again there is no reason why it should not follow the same course as far as duration is concerned. In the plague of 1592–93 the visitation began in the first year, then died away, recommenced in 1593, and did not afterward recur. The visitation in 1603 lasted for one year only. The visitation of 1625 lasted for one year, but there was a recurrence of it in the year 1630, and thereafter it was intermittent for about twenty years. It then disappeared until 1665, when it lasted until the winter of that year, and then disappeared altogether.—*London Times.*

**Dangers of the Plague on the Pacific Coast.**—Dr. V. C. Vaughan contributes to the *Popular Science Monthly* an article entitled "Are We in Danger from the Plague?" After reviewing at considerable length the history of the present epidemic and the means of prevention and treatment he answers the question as follows: "I will have to answer this question very much as I did two years ago: 'Yes, we are in danger, but this danger, being foreseen, may be easily avoided.' In my opinion our most vulnerable point is along the Pacific coast. With the plague at Hong Kong it is possible that it may be transferred to Manila, and the transports bringing soldiers to this country may also bring the infection. However, I think the chances of this happening are small. The length of time required to make the voyage from Manila to San Francisco is so great that with the infection on board it would be almost certain to manifest itself before reaching our shores, and knowing its presence on board a ship reaching San Francisco or any other point on the western coast, thorough inspection and disinfection will keep the disease out of this country. The probabilities are that for several years to come the larger cities of India, at least, will remain infected, and our sanitary authorities must be vigilant. The facts that if the plague reaches us at all it must come by sea, that a long voyage must be made before it can reach us, and that the disease will most probably appear on board ship before arrival at any American port—all

these conditions are in our favor. The general government should take upon itself the control of all measures to prevent the introduction of infectious diseases from without. Quarantine detention is a relic of ignorance of the true nature of infectious diseases. All transports and other vessels should be provided with proper disinfecting apparatus. The government should supply the Marine Hospital service with every needed equipment, and if this is done the plague can enter America only through incompetency in the service. There is another source of danger on our western coast that must not be overlooked. The plague is now widely distributed in Formosa, which is under the control of Japan, and our intercourse with the last-mentioned country should be most carefully watched."

**Influence of the Weather upon Crime.**—Edwin G. Dexter writes an article on the above subject in the *Popular Science Monthly* for September, and concludes that the tendency to homicide varies with those meteorological conditions which bring about an emotional state necessitating a considerable discharge of motor stimulus. The same conditions bring about irritability and unruliness in the child, accompanying suicidal tendencies. This supposition is upheld by the fact that suicide is less common in the colder climates where the metabolic processes are slow, and in the torrid zone where the heat produces a general depletion of energy for motor discharge, than in the temperate regions where the climate is exhilarating.

**New Explanation of the Presystolic Bruit.**—Dr. C. C. Gibbes, writing on this subject in the *Clinical Journal* of July 12, 1899, draws the following conclusions: (1) In consequence of the different tensions existing in the right and left ventricles, these cavities under the circumstances of mitral constriction do not act synchronously. (2) The base to apex portion of the right ventricular systolic wave occurs when the left ventricle is in diastole. (3) The right ventricular muscle vibrations are heard during the diastolic period, and they gradually increase in intensity toward the end of it. (4) The so-called presystolic bruit is composed of three parts: (*a*) right ventricular muscle vibrations; (*b*) an auricular systolic bruit; (*c*) a slapping first sound, the muscle vibrations being the cause of the peculiar and intimate relation between the bruit and that sound. (5) In the double mitral murmur these vibrations prevent the distinction between the two murmurs which is heard in the double aortic murmur.

**Endometritis, Congestion, or What?**—In an article on this subject in the *Yale Medical Journal* for March, 1899, Dr. Barber concludes as follows: (1) Simple endometritis, uncomplicated, is rare; a leucorrhea, when present, is not indicative of it, without the presence of micro-organisms, which would argue that all scrapings should be microscopically examined for correct diagnosis. (2) Gland-tissue disturbances of the endometrium, whether from congestion or lack of blood supply, is not, according to Welch, an inflammation, and therefore not an endometritis, in the true definition of the term. (3) Such disturbances are better and more scientifically treated from the medical than from the surgical standpoint. (4) The curette, a powerful factor in the treatment of some forms of endometritis, is not curative in this form, and is, according to good authority, used much too frequently without due reason, and often by the irregular with criminal intent.

**Practical Aphorisms.**—Dr. H. A. Hare says that there are two aphorisms which he is in the habit of emphasizing to his classes—one is that "when called to care for a patient through an attack of illness the physician should be a watchman all the time, and a therapeutist only when necessity arises." Surely, he says, there is no disease commonly met with in which this holds true more than it does in pneumonia. The second is that in all acute infectious diseases, and particularly so in croupous pneumonia, patients may be divided into three classes, namely, those who are so mildly ill that all they need is good care and little or no active treatment, cases on the contrary so malignant that nothing can be done which will produce cure, and a third class which, lying between these two types, is capable of cure, but only when the individual is aided by the most skilful treatment.—*Therapeutic Gazette.*

**Charcot as an Artist.**—It is related of Charcot, the distinguished alienist, that he had marked artistic ability, and that when he was seventeen years old his family had some hesitation whether to make him a doctor or a painter. He chose the medical profession. He was fond of drawing sketches of his patients and of landscapes he saw in his travels, and was not above making an occasional caricature. Several albums are filled with designs of this kind. A study of his work as an artist was prepared by Dr. Henri Meige in connection with the erection of his monument, and is deposited in the Salpétrière.—*Popular Science Monthly.*

**Literary Malaria.**—Literary malaria is thus diagnosed by Mrs. Earle in the *Book Buyer:* "Literary malaria is the state of strain and bewilderment, involving an inability to do creative work, which is brought about by poring on old books in search of local color and illuminating facts. It is a disease most incident to historical novelists. The preliminary dive into history may be delightful, but the result is that the brain is fretted by the search, especially by defeat in the search, and the result of digging in this humus of decayed literature is a 'fever and ague' of the mind. The material is there, and it sends up exhalations that seem of themelves to form shapes and dramas that only require the aid of the pen to record them; but a subtle undermining of the executive power of the brain has been going on, and the old musty styles which will never do for modern readers go singing through the brain and obsess it."

**A New Remedy for the Phylloxera.**—The Italian minister of agriculture and several scientists of that country are engaged in testing a medium which is to protect the Italian vineyards from the ravages of the phylloxera. This remedy was first employed by the vintager Lauro D'Angelo on Elba. It consists of copper sulphate, and its application is exceedingly simple and cheap. According to the *Naturwissenschaftliche Wochenschrift*, the plants are sprinkled with dissolved copper sulphate and some is thrown on the ground in a powdered state. By the rains in fall, winter, and spring, the powder is dissolved and enters the soil. The method employed by D'Angelo consists in giving the vines first the liquid treatment, followed by five with the powder. In the former case there are used one per cent. of lime, 1.8 per cent. of copper sulphate, per one hundred kilos. of sulphur; in the second case the vine plants receive two treatments with two per cent. of copper sulphate and three with five per cent. to every one hundred kilos. of sulphur.—*Scientific American.*

**Works of Art from a Psychological Standpoint.**—Even works of art cannot escape from the psychologist and the medical man. Dr. C. H. Stratz points out some curious symptoms of disease in types represented in works of art. He finds that Botticelli's Venus in the Uffizi at Florence is suffering from consumption.

and should not be riding across the sea without clothing. It is needless to state that nothing of this kind was ever attempted by the old masters; they selected types which appealed to them, and painted them as they saw them, and it is practically time wasted to hunt up hidden meanings in works of art.—*Scientific American.*

**Tuberculosis in the German Army.**—The *Militär-Wochenblatt* publishes an article on tuberculosis in the German army, from which it appears that the number of cases has fallen from 2.9 per 1,000 in 1890–91 to 1.8 per 1,000 in 1889–99, the death rate for the same periods being 0.24 per 1,000. In the Bavarian army the decrease in cases has been 2.3 and the death rate 0.32 per 1,000. The number discharged from the German army on account of the disease during the five years ending in 1896 was 7,205, or 51.9 per 1,000 of those discharged for any reason whatsoever. It must be remembered that no man is admitted into the army who in the medical examination which precedes entrance is found to be suffering from the disease; apparently, therefore, it is contracted in the army. The chief predisposing cause is stated to be a "cold"; the next in importance is the strain of military duty, but this does not include the blowing of musical instruments, which comes under a separate heading. The treatment pursued was more or less successful in 23.3 per cent. of the cases. In 1.2 per cent. a perfect cure was effected. In the remaining 76.7 per cent. the treatment failed, and death resulted in 16.1 per cent. The decrease in the number of cases in recent years is attributed largely to the discovery of the bacillus of the disease by Koch in 1882, owing to which it is easy to detect the disease and reject recruits suffering from it who would otherwise have passed the medical examination.

**Health Reports.**—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended September 15, 1899:

**Tobacco and the Latin-American Race.**—It is feared that over-indulgence in tobacco may have a prejudicial effect upon the Latin-American peoples, especially those in South America. According to *Prometheus*, not only do children of two or three years smoke all day long, but mothers have been seen trying to quiet their babies by putting cigars in their mouths.—*Scientific American.*

**Thucydides on the Plague.**—In the detailed account given by Thucydides of the plague at Athens, B.C. 430, though we cannot with certainty identify the disease, it is clear that it was considered contagious. It was supposed to have come from Ethiopia to Egypt and Lybia, whence it passed to Persia, taking Lemnos on its way, from which it fell on Athens. Afterward when Hagnon went with forces to help the Athenian army at Potidea he took the disease with him, so that ten hundred and fifty out of four thousand perished in forty days.—*The Medical Magazine.*

**Examination of Liquors.**—By having liquors examined, and only pure liquors sold and condemned liquors destroyed, precisely as in the case of unclean or impure meats, milk, fruit, and confectionery, much could be practically and in a minimum lapse of time accomplished for the decrease of the liquor evil. The Prohibitionists themselves, by placing, replacing, abolishing, and experimenting with all sorts of statutes on the statute book, have accustomed us to state regulations of the sale of intoxicants, and least of all can complain of yet one more experiment toward the decrease of drunkenness.—*Popular Science Monthly.*

### A FURTHER VIEW OF THE MANAGEMENT OF THE DEFORMITY OF HIP DISEASE.[1]

BY A. B. JUDSON, M.D.,

NEW YORK.

HAVING tested by further experience the value of a promising method of preventing and correcting the deformity of hip disease, I desire to call attention to the subject again. In a paper read before the association in 1889 a number of clinical facts were set in order, and from them deductions were made in favor of this method, which, omitting preliminary and argumentative matter, may be said to consist in the education of the patient,

Case I. Photographed 1899, twenty years after treatment. Age, twenty-nine years.

wearing the hip splint, to the habitual observance of the normal rhythm of human locomotion. At the risk of repetition I recall a few points.

The deformity and factitious shortening are caused by the patient's instinctive and habitual effort to keep the affected limb clear of the ground by elevating the pelvis on that side, with adduction as a necessary accompaniment (flexion and adduction are here considered in the same category). The patient does this to escape the pain which might come from a sudden and unexpected contact of the foot with the ground, and also to withhold the bad foot from the ground in favor of the well one, which hastens forward to do the work. The result is that the affected foot visits the ground for a moment only, while the well one lingers on the ground, and the natural rhythm, or time, is destroyed. True time may be expressed as follows: "One—two—one—two—one—two—one—two," and false time thus: "One–two—one–two—one–two—one–two—one–two." It is found that if the patient gives up false and resumes true time, which can be done by an effort of the will or as the result of drill, the affected limb gives up some of its adduction and flexion in order to reach the ground more conveniently to do its share of the work. With this come also horizontal adjustment of the pelvis and a decrease of shortening.

Violation of rhythm and the deformity appear to be incidents of nature's method of protecting the diseased joint from pressure and concussion by transferring a large part of the work of locomotion from the affected to the sound limb. One of the advantages of treatment by the ischiatic crutch is that it furnishes complete protection with a return to natural rhythm and release from adduction, apparent shortening and tilting of the pelvis. This will demand an apparatus strong enough to give to the body the support which it is accustomed to receive from a well limb.

Patients who have recovered with serious lameness, when instructed in this simple mystery, have overcome a large part of their lameness and deformity by learning to observe natural time in walking, an improvement which could not be expected, of course, if bony ankylosis were the result of hip disease. It is an

[1] Read before the American Orthopedic Association, at New York, June 2, 1899.

interesting fact that throughout the early and active stages of the disease the position of the limb readily yields without pain to a slight amount of continuous

Fig. 5.

Fig. 6.

Case II. Duration of disease before treatment, one year. Under treatment, two years seven months. Photographed in 1880, eight months after treatment. Age, six years. Examined 1899, twenty years after treatment. Age, twenty-six years. Condition like that of Case III. in 1899, excepting that there is one and one-fourth inches of real shortening.

force. Even after recovery the condition is far from immobilization or intractable fixation.

It may be said, by the way, that the rhythm of human locomotion is a subject which has probably not received the attention to which it is entitled. The very simplicity of the normal rhythm makes a slight deviation from it very noticeable, as in the incipient lameness of a child who simply accentuates the blow given to the ground by the hastening well foot. Violation of rhythm is one of the constituents of lameness. Lameness in general is essentially asymmetrical walking, complete symmetry of gait requiring similarity of the two limbs not only in their length and relation to the rest of the body but also in their movement. It is a point of practical importance that the lame needlessly add to their lameness by neglecting to keep correct time with their feet. A well person can pass for lame by the simple device of giving more time to one foot than to the other, a matter capable of instant demonstration, and one who is seriously lame can lessen the appearance of being so by habitually observing the natural rhythm of locomotion. If the trouble is the result of hip disease, not only is the appearance improved, but the cause of the lameness is by this method lessened with the removal of adduction and undue flexion.

This method is naturally placed in comparison with operative correction. Warm personal regard for Dr. V. P. Gibney would make me hesitate to differ with him in opinion. He will, however, enjoy with me the humorous element which comes to light in his having referred to the wrong boy in his argument in favor of operating for the correction of these deformities. In giving the previous history of one of the cases in which he had operated with excellent success he says: "Dr. Judson finally succeeded in arresting the disease, presenting his case as cured in a series reported in volume II. of the Transactions of the Academy."[1] This boy was, indeed, badly deformed, with good reason as will appear further on, but he was not in the series presented to the Academy. The patients so presented recovered with but little flexion and adduction. Their present condition is shown in the accompanying cuts.

The boy on whom Dr. Gibney operated had been described by me as showing bad deformity, the result of careless walking, in the following words. In the same connection I referred to two other patients who had avoided deformity by walking symmetrically. I reproduce the whole passage substantially as follows:

"Why do patients similarly affected and treated exactly alike recover with such different degrees of deformity? A young girl, for instance, was in the third stage before treatment was begun in May, 1880. She has recovered with no adduction, almost no flexion, and with very little lameness. I attribute this good position to the fact that her mother was very anxious about her only daughter, and was always with her, so that every step the child took, wearing the hip-splint, was taken under the necessity of appearing as well as she could. Her steps were timed equally, and her affected limb assumed and retained a useful position because it had to do, so far as was possible, one-half of the work of locomotion.

"A boy recovered (treatment begun June, 1883) from the disease in a more moderate form, but he limps about most awkwardly with 20° of adduction and 50° of flexion. I explain his bad position by the fact that his mother, one of the best women in the world, was busy out of the house every day, leaving at home all day her family of four boys. As the patient was most of the time in excellent general health, he vied with his brothers in all their games and developed his well limb at the expense of the affected one, which was elevated and adducted to keep it out of the way.

"In another case (treatment begun November, 1883) the patient, who recovered after long-continued purulent discharges, was a girl endowed with uncommon beauty, and although she was by no means docile, and under very little restraint at home, her vanity led her

Fig. 7.

Fig. 8.

Case III. Duration of disease before treatment, four years. Under treatment, four years. Photographed in 1879, eighteen months after treatment. Age, thirteen years.

to try to appear to the best advantage, and, thanks to her careful gait and studied attempts to be graceful, she now walks with very little lameness, with flexion not more than 10°, and no adduction.

[1] Transactions of the American Orthopedic Association, vol. vii., 1894, pp. 195–197; The International Medical Magazine, Nov., 1894, vol. iii., pp. 713, 714.

"I advise especial attention to the manner of walking, insisting on the patient's keeping time in his steps so far as is practicable, and leading him to adopt a proud bearing. A girl is told to practise deportment before a looking-glass, and the parents are informed of the importance of encouraging the child to adopt deliberate and graceful movements on all occasions." [1]

These views[2] have been but confirmed by intervening experience. Intractable cases will occur, exceptions perhaps to prove the rule, like that of the boy referred to. For him there was no resort except to operative correction, which was well done by Dr. Gibney, as shown in the photographs which form a part of his valuable paper.

The series referred to, showing the results of treatment in severe cases, was reported to the Academy in April, 1880.[3] Their condition at that time and also twenty years later is shown in the cuts so far as photographs could be obtained. These patients were all

Fig. 9.

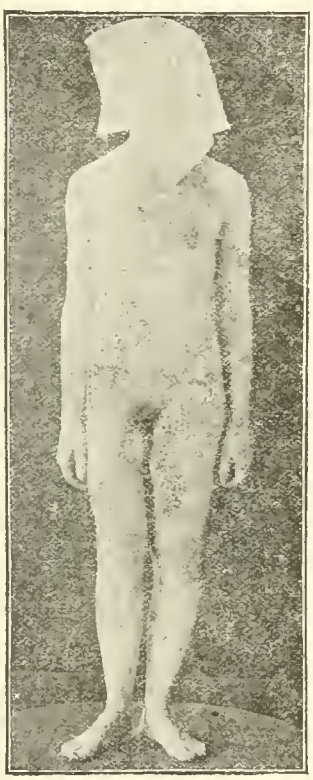

Fig. 10.

Case III. Photographed 1899, twenty-one years after treatment. Age, thirty-three years.

advanced in the third stage in its worst features before treatment was begun, and their recovery was something in the nature of a surprise. In fact the series would have contained four cases if a patient similarly affected and under treatment had not died of tuberculous meningitis.[4] The method is applicable as well to cases of moderate severity, a number of which were reported in the *American Medico-Surgical Bulletin*, January 1, 1895, vol. viii., pp. 4-6.

In orthopedic charities, where patients equipped with the ischiatic crutch might be formed into companies, military drill would doubtless do much toward securing a final good position of the limb, remembering that complete success will depend largely on an exact adjustment of the apparatus. In cases of recovery with normal motion in the joint the question of the management of deformity is happily shut out.

## THE NEGLECT OF SEXUAL SYMPTOMS IN THE TREATMENT OF THE MALE GENITO-URINARY ORGANS.

By FOLLEN CABOT, M.D.,

NEW YORK,

INSTRUCTOR IN GENITO-URINARY AND VENEREAL DISEASES IN THE POST-GRADUATE MEDICAL SCHOOL AND IN THE CORNELL UNIVERSITY MEDICAL COLLEGE; GENITO-URINARY SURGEON TO OUT-PATIENT DEPARTMENT, BELLEVUE HOSPITAL.

In private and dispensary practice during the past five years I have been called upon to treat a large number of patients affected with various forms of sexual symptoms. Many of these patients have given a history of some form of venereal disease of their genito-urinary organs, but a considerable proportion have never had any venereal disease whatsoever. A large proportion of these patients have been treated by reputable physicians, specialists in genito-urinary diseases, and also by general practitioners. The point about the condition of these sufferers which has impressed me most strongly was the apparent neglect, by many of these medical men, of important sexual symptoms. Why have these symptoms been so ignored?

For several years I have studied the subject very carefully, and have come to the conclusion that, as a rule, medical men do not study, largely from a lack of opportunity, sexual hygiene, and as a consequence the importance of such matters are little appreciated or understood.

That the sexual apparatus is of vast importance few of us will deny. Many of the specialists in genito-urinary diseases are in reality urinary specialists so far as their knowledge and treatment of the genito-urinary tract are concerned. I do not believe in placing sexual symptoms in the foreground and considering them alone, but I do plead for a much more scientific study of the sexual organs in health and disease, than has been accorded them up to the present time. Some of the causes of the suppression and belittling of disturbances of the sexual system I believe to be the following:

First: From childhood to the time of puberty the majority of children, boys and girls, are taught absolutely nothing about sexual hygiene. They have to learn by their own experience one generation after the other. There is a deep mystery cast over the whole subject, as if it were something improper and indecent to discuss, even between father and son or mother and daughter. Is it any wonder that wrong ideas are received, injurious acts performed, and children grow to adolescence with crooked and misshapen ideas in regard to a function which is next to self-preservation in importance and intensity? If parents clothe or feed their children improperly they usually find it out and correct the error. When, however, it comes to a question of sexual hygiene we immediately tread on forbidden ground, and ignorance and mystery reign supreme. This lack of proper sexual teaching in youth undoubtedly affects both physician and patient in after-life.

Second: How much is taught in our medical schools on the sexual function and its relation to health and disease? Practically nothing. If the subject is broached to a patient before a class of medical students or even graduates in medicine, it causes a general smile of ridicule from the students, and the patient crawls into his shell. If he proceeds, and in answer

to questions explains his sexual symptoms, he is the object of more ridicule. Of course it is a delicate subject, but is that any reason for keeping the very important function enshrouded in mystery and bringing harm and suffering to the ignorant? There is undoubtedly room for delicacy and proper modesty, but cannot we have these and yet get at the reasons for the patient's sexual disorder?

Third: The sexual instinct being for many reasons associated with the most sacred relations of life, people as a rule, even if in some particulars sexually disturbed, prefer from natural causes to say nothing. If they do consult a physician they are liable to say something misleading unless drawn out by a medical man who has knowledge of the subject, tact, and patience all combined. He must also be possessed with ideas of the importance of the derangements of this function, otherwise he can accomplish little. With the patient's confidence, as in many other disturbances, but more particularly in sexual matters, half the battle is won. Many genito-urinary physicians, however, make light of the whole subject before the patient has had a chance to tell his story. Others, without making a physical examination, and after gaining a few points which they think indicate mental or nervous disease, turn the case over to a specialist in nervous diseases. In some cases the physician may be right in his guess, but not right in knowing so little about his patient's condition.

Many of these patients have functional disturbance of the sexual organs which can be detected by a skilled examination. Patients of this last class of cases, who can be relieved only by local treatment, are thus passed on to a nervous specialist, who, of course, does not pretend to give local treatment, and the patient is not relieved. He may then drift into the hands of a quack, where he at least gets sympathy, for he is allowed to tell his story, he may also receive some sort of local treatment used in a blind way by the quack on general principles. He also may receive an electric belt which he wears night and day for the next ten years. In this way the patient may receive benefit, but more often is simply fleeced by his sympathetic quack adviser.

These sexual cases constitute a large body of patients which should be treated by the legitimate profession; instead of which they are buffeted about from pillar to post. That they are difficult cases to manage I do not deny, but we of the legitimate profession should make more of a study of them, and relieve if not cure many more patients than we do at the present time. The time has already come when the regular profession has begun to treat patients with disturbances of the genital organs in a much more scientific and thorough way. This class of patients is being looked upon more and more each year as we look upon other patients, and is being treated after improved methods, in many instances with most satisfactory results.

Dr. Eugene Fuller, whom I have assisted in private and hospital work for several years, was the first to call attention about seven years ago to certain conditions of the sexual apparatus which involve the seminal vesicles, producing the most varied nervous and general symptoms. Later Dr. Fuller wrote a book entitled "Disorders of the Male Sexual Organs," in which is given in a thorough and scientific manner a careful study of the physiology, pathology, and treatment of the seminal vesicles. The treatment outlined in this book has done a great deal to relieve and cure a large class of formerly much-neglected sufferers. Many other physicians have taken up this treatment and written on the subject. It is a treatment, however, which requires special training to be effective, and this special training can be gained only by the routine examination of a large number of patients, otherwise the form of treatment as recommended by Dr. Fuller will not be successful.

The number of patients with urethritis seriously damaged in their genital apparatus by improper and violent methods of treatment I believe to be large. I am positive from my own experience and from other sources that the Janet method of irrigating the urethra and bladder has been the cause, directly and indirectly, of much damage to the sexual organs. In a small number of selected cases I believe the method to be of use. I do not believe, though, that it is a desirable form of irrigation for the majority of cases of urethritis. If we had to contend only with a urinary tract the method would be perfect. But when we consider the complex genito-urinary apparatus, the various organs in direct and indirect relation to the urethra, we should hesitate before applying this treatment indiscriminately. Many of the cases of urethritis treated by the Janet method of irrigation have been apparently cured in short order. The superficial observers may proclaim with loud voice that the great cure for acute urethritis has come, but the observer who looks underneath, and who sees many of these cases afterward, will be satisfied that frequently much damage has been done to other organs, mainly genital, which is of a serious nature and difficult to relieve.

In a limited number of cases in which the urethritis is in the front urethra, applications in the first twenty-four hours directed to this part alone may produce a rapid cure. The term urethritis is used by me to designate the two classes of cases, in one of which we find the gonococcus and in the other we do not. It may be well to say in passing that the methylene-blue stain alone is not reliable, for in order to be sure that we are dealing with the gonococcus we should use the Gram strain as a final test. The decolorization of the diplococcus shows it to be the specific micro-organism of gonorrhœa. Dr. Henry Heiman brings out this point in a very convincing way in his well-known study of the gonococcus.

There is a third class of cases, in which there has been no discharge either of a specific or non-specific nature, but in which the sexual organs have been injured by improper methods of intercourse. Cases of this class demand the exercise of considerable skill on the part of the physician in order to arrive at a correct diagnosis.

The three classes just briefly described are all amenable to some form of local treatment, except when there is a tuberculous condition present, in which event all local treatment should be discontinued.

The history of the following case will give an idea of some of the symptoms present in a patient first infected with gonorrhœa and later manifesting symptoms produced by local disturbances in the sexual organs:

Case I.—G. C——, aged thirty-five years, tailor, unmarried. The disease began with a specific urethritis two and one-half years ago. He was treated by a physician for five weeks with urethral irrigation. He improved very much, with disappearance of the discharge. The discharge returned in two weeks without known cause. He went to another physician, and was told he had cystitis. There was much pain in the lower abdomen, frequent urination, and free discharge. He did not improve, so he went to another physician, who gave medicine and later a front injection. He was better at first, then worse again. He went on in this way for six months, when he came to me. When I first saw him he complained of dull pain in sitting, in the region of the anus and perineum, with great discomfort from itching in the rectum. He had a few feeble erections, with some discharge. He was very nervous and apprehensive, and could not attend to work. Examination showed the seminal vesicles to be inflamed and thickened; very sensitive, especially

on the right side extending into the prostate. The perivesicular tissue was involved about both vesicles; otherwise examination was negative. The vesicles having been stripped once in five days for two months by me, all symptoms disappeared, and the discharge ceased. But he was still in need of more treatment to cure his condition entirely, when the patient suddenly ceased his visits. He afterward told me he did so because he thought he was well, and was anxious to try his sexual power again; but indulgence brought back a discharge in twelve hours and pronounced general nervousness. As he had disobeyed orders he was ashamed to come back to me. He went to another physician, who passed sounds first, and then gave the regulation treatment, an injection to use at home. Double epididymitis followed, which became better in ten days, but he had fearful itching and pain in the region of the anus and perineum. There were no erections. He was extremely nervous and very much depressed about his sexual power. He had no nocturnal emissions for several months. This condition continued for about a year or longer. In the mean time the patient went to the country to live and tried several physicians. Up to three months ago, when he saw me again, he had been to eight specialists. His condition when seen by me three months ago was as follows: The urine showed some threads, was not cloudy, he had no apparent discharge; no gonococci were found in the urine as passed at first. Examination showed the prostatic region to be sensitive, the seminal vesicles were both thickened and bound down by perivesicular tissue; they were not much enlarged, but rather sensitive to manipulation. The stream of urine was of normal size. The endoscope showed the urethra to be normal. The patient was extremely nervous, he had pains in the legs, hot flashes over the whole body, and was very apprehensive and depressed; he had poor erections, with failure on attempted intercourse.

The vesicles were stripped gently each five days. Some purulent material was expressed, under the microscope showing a macerated state of spermatozoa: no gonococci were seen. Immediate relief followed the first treatment, and improvement has been constant, with return of good spirits and sexual tone. This relief lasts four days; then he begins to feel return of the old feelings, when another treatment is given with immediate relief. He was advised to have sexual intercourse every two weeks with the use of a protector. No sounds have been used in this case by me. A tonic was also given, but the stripping has been the only treatment in his varied experience which has helped him. He has gained eight pounds. It will probably take from six to ten months to cure this patient completely. This case is not unique by any means; in fact, it is one of a large class. I believe this man to have had but one infection of gonorrhœa, but that it was driven into the sexual organs by improper treatment, such as irrigation and sounds. I feel sure that if he had finished his first course of treatment with me two years ago he would then have been cured.

Case II.—This was a case of a man in whom there was no history of venereal disease. G. M——, aged thirty-three years, clergyman, unmarried. He never has had sexual intercourse. Seven years ago he began to have irritation in the bladder, with slight pain in the neck of the bladder and rather frequent micturition. For a year, he passed the sound himself daily; he also has had the bladder washed out several times, but with no relief. He has very frequent nocturnal emissions, three to four a week. Examination was negative except for lack of tone in the region of the prostate and seminal vesicles, with considerable pain on pressure over the lower portion of the vesicles, which were bound down by old inflammation. I began treatment December 5th last, and at first little improvement followed stripping. But soon relief began to follow each treatment, so that this procedure was essential to the patient's comfort. After a few months large particles of inflammatory material were expressed with each stripping. The general tone of the patient has much improved; the irritation is nearly gone, and nocturnal emissions occur only one-third as often. He can now, before feeling discomfort, go a month without a stripping, and the interval is gradually lengthening. He has now been treated by me for eight months. He is much more buoyant, and the sense of irritation evinced by frequent urination has gone. Besides this treatment as described he has been given cod-liver oil and frequent rectal irrigations to relieve constipation.

These two cases give a good idea of the sexual symptoms seen in gonorrhœal and non-gonorrhœal cases when the disturbance is to be found in the sexual organs.

We must always remember that there may be a disease of the urethra or other neighboring organs at the same time that there is a disease in the genital apparatus. If so, this must also be treated. We may have a deep urethritis, or inflammation of the ejaculatory ducts, etc. In such cases we may have to use in addition deep injections, applications through the endoscope, etc. The urine should always be carefully examined to help us arrive at an opinion as to the present cause of a discharge and any other evidence of disease, and to treat the cause of the trouble and not the effect. The discharge in itself is of no importance as a discharge, but it is the diseased region we should treat, after a careful and scientific study of the case from all sides. If the genital organs per rectum are found to be normal, we may then proceed to examine the urethra and other regions as indicated by the history of the case. An injection should not be given immediately on finding evidence of a discharge. The seat of the trouble should be treated. We have come to a time when such empirical methods are not justifiable.

The two cases I have reported have been stripped regularly every five days, and occasionally the result of the strippings have been examined microscopically to see how the condition of the vesicles changes.

In the cases with a gonorrhœal history the expressed vesicular material should be taken from the urine by the centrifuge and planted on chest-serum agar as the only positive method in chronic cases of determining whether or not the gonococcus is still present.

Stripping of the seminal vesicles in some cases will increase a discharge for a time as the contents of the vesicles become softened. This need cause no worry, but should be looked on as a good sign, particularly if the discharge at the same time becomes thinner. From the first few strippings we may obtain little result. As the vesicles become softer the contents are more easily expressed.

Good results cannot be obtained by this method of treatment till a thorough course of training the finger has been completed. This fact accounts for some of the unsatisfactory results obtained by those unfamiliar with the conditions found per rectum.

In conclusion I repeat: (1) Sexual symptoms in genito-urinary practice should be carefully investigated and thoroughly studied.

(2) Indiscriminate use of irrigation is distinctly against scientific teaching, its effect on the genital organs often being injurious and causing the spread of the gonococcus.

(3) Before urethral instrumentation is employed every case should be examined per rectum with a finger educated to the rectal touch.

(4) Various forms of remote nervous symptoms are directly traceable to disorders of the sexual organs.

128 East Thirty-eighth Street.

## THE INDUCTION OF PREMATURE LABOR IN CASES OF ALBUMINURIA.

By ELIZABETH JARRETT, M.D.,

NEW YORK.

The scope of this paper is far more limited than the first part of its title would imply. To cover the entire question of the induction of labor prematurely would necessarily involve:

1. The consideration of all the conditions which in modern obstetrical practice would be deemed indications for this step, such as acute or chronic renal troubles, dystocia, chronic cardiac or pulmonary disease, uncontrollable vomiting, etc.

2. The best method of inducing labor under each and every one of these conditions.

Questions so broad could not be compassed in a brief paper like the present, which will deal with only one phase of the subject, namely, the necessity for the more frequent application of this method (*i.e.*, forced delivery) of relieving the pregnant uterus in a patient suffering from chronic renal lesions, with a brief consideration of the best method of procedure under such conditions.

There is no condition which an obstetrician more dreads to meet, nor one which calls for more earnest and thoughtful study, than that group of symptoms which point to impending eclampsia. From the time that albumin is discovered in the urine of the pregnant patient there is no peace of mind for her physician until the ordeal of labor is not only passed, but well passed. He may console himself temporarily with statistics as to the number of women whose urine presents albumin in greater or less quantity, who yet pass through their labor without a symptom; he may try to convince himself that the policy of non-interference has many adherents among those foremost in the ranks of obstetrical authority; he cannot disabuse his mind of the conviction that he, as well as they, are laboring absolutely in the dark, in default of any accurate knowledge as to the etiology of this much-to-be-dreaded accident, and that in any single case he knows not where he stands. He dare not give a prognosis—he can only be on the alert, and work and hope for the best.

Apart from the question as to the probable outcome of the case if left to nature—that is, of course, with the proper and necessary medical supervision—is that other question as to whether a more positive course should not be taken out of regard for the mother's future welfare. This course may or may not be the death warrant for the child, according to the period of gestation and other conditions; danger to the child and its possible death it always means, hence the degree of hesitation one always feels in sanctioning a positive course.

The induction of premature labor, as a rule, for the prevention of eclampsia, in cases presenting albuminous urine deficient in urea, has many opponents. Dr. Fordyce Barker, in an article in the *Journal of Obstetrics* for July, 1878, takes a most conservative stand; but he, as well as others, seems to regard the matter entirely with a view to the prevention of eclampsia. This accident having been successfully avoided, the condition of the patient is presumably as good as is to be expected. Not a word is said as to any permanent damage done to the kidneys by allowing the pregnancy to continue uninterrupted. Convulsions have been avoided, and the case is a success.

Not all cases of albuminous urine terminate in eclampsia; not all cases of eclampsia terminate fatally, either for mother or child. Statistics as to the proportion vary so much as to be wellnigh unreliable, and I shall make no attempt to quote them. Each case must be judged on its own history and its probable chances of safety, not only for the mother's life, but for her future well-being.

There are, to my mind, indications which point so unmistakably to danger for the mother that the question of the induction of labor prematurely should be seriously considered, and I think decided in the positive more frequently than it now is. This seems a very radical stand to take, but I take it on the ground that not only is the life of the mother of more importance than that of the unborn child when it is a matter of the life of one or the other, but further, that the future good health of the mother should weigh more than the life of the child. If to carry a child to term means to shorten by many years the mother's life, then the question of terminating that pregnancy before serious damage is done should be most carefully considered.

The theories as to the causes governing the onset of eclampsia have been very numerous. Dr. John Byers, in an article in *The Lancet* (April, 1897), has grouped them under the following heads:

1. The reflex neurosis theory, which, briefly stated, claims that a reflex action on the sympathetic and the renal nerves is set up by the new condition in which the uterus finds itself.

2. The kidney theory, which calls special attention to the presence of albumin in the urine, and to the failure on the part of the kidney to eliminate certain excrementitious products, as urea, kreatin, etc.

3. The toxæmic or blood-poison theory, which asserts that nerve centres are poisoned by a toxin, the product of ordinary retrograde metabolism of both mother and child, which is usually eliminated without undue effort, but which, if the eliminating organs fall short of their allotted task, is stored up until its auto-intoxicating action is manifested by eclamptic symptoms.

It would be most interesting to take up, seriatim, the arguments for and against these three theories. This Dr. Byers does in his paper, and decides in favor of the toxæmic theory as covering all cases, even those not presenting albuminous urine before labor. With his conclusions I cannot altogether agree. The more I study the question as presented by individual cases, the more I am convinced that different factors will be found at work in different cases.

Often it would seem as if a combination of two of the causes so clearly defined by Dr. Byers could be made out. For example, how explain the revolt of the kidneys in the very early months of pregnancy? Could the comparatively slight increase of real eliminative work thrown upon them by the pregnant condition cause such marked symptoms of gastric, intestinal, and renal irritation as are sometimes seen, unless the theory of reflex nervous disturbance throws some light upon the question? The condition of the uterus during normal menstruation would seem to be not far removed from that during the first six weeks of pregnancy, yet whereas no symptoms may be present in the one case, numerous reflexes are at once inaugurated by the conditions attending pregnancy. Of course this statement does not hold in the great majority of cases.

Whatever may be the causes at work in different cases, there is a distinct class of cases in which the trouble can clearly be made out, and it is to this class and to its conduct that I would particularly call attention. The cases to which I refer are those in which a decided kidney lesion can be determined by chemical and microscopical urinalysis. That albumin may exist in the urine and sometimes in considerable quantity as a merely functional condition, most pathologists will admit, and while an obstetrician would watch this feature with more than ordinary care, he would, I think, scarcely be justified in suggesting premature delivery on this ground alone.

But when, in addition to the albumin present, there is found evidence of a nephritis, acute or chronic, the question is altogether different. Here is no functional trouble to be relieved, as is a transitory albuminuria upon the conclusion of labor, leaving no permanent trace, not even recurring in future pregnancies. Here is evidence of an organic lesion, affecting one of the great eliminative centres of the economy, and the question is, What is to be the result of pregnancy completed to full term upon these organs?—not the immediate effect. Not every woman surrenders at the time of labor to these conditions—but what are the effects upon her future well-being? Statistics do not follow up these cases. The same physician does not always have the opportunity of watching them through successive years, or even through successive pregnancies. To my mind, there is no question that a pathological condition has been set up, or, being yet latent, has been brought to light by the pregnant state, whose results are disastrous in direct ratio as the condition is allowed to remain, unrelieved by the termination or removal of its cause.

No one would take the ground that the induction of premature labor in cases suffering from nephritis means the cure of the kidney lesion; what we do mean is, that in some way which we do not as yet thoroughly grasp, the existing pregnancy makes increasing demands upon the organs of depuration, throwing upon them a burden which they are totally unable to sustain, until the strain ends in such a hopeless crippling that no amount of care during or following labor is sufficient to restore them to their original degree of usefulness. Is it not then the most conservative, though at first sight the most radical, plan when we find the burden of pregnancy either developing or extending an already existing nephritis, to remove the cause of the trouble? The strain of a few months of pregnancy must be equal to years of ordinary wear and tear.

It would be a most valuable contribution to obstetrical literature if those whose practice in this direction is large, and covers more particularly successive pregnancies in the same patient, were to give us carefully recorded observations as to the condition of the kidneys in those patients whose urine has in one or more pregnancies exhibited albumin alone, as well as the condition of the kidneys in patients one, two, or more years after a labor complicated by decided kidney lesions. Such careful reports would be of great value in deciding upon the best course to pursue in any given case. That there is no well-grounded consensus of opinion as to the urgency of a positive course when a well-marked kidney lesion exists, was forcibly demonstrated to me recently by the difficulty I experienced in getting men upon whose judgment I relied to approve of the induction of labor in a case in which it seemed urgently demanded. Theoretically, yes, it was the approved course; practically, would it not be better to wait for the viability of the child? Yet the patient was laboring under an organic heart trouble, mitral and aortic regurgitation with left ventricular hypertrophy, an acute hemorrhagic nephritis grafted on to a chronic condition, cystitis, and a left inguinal hernia.

In a paper read before the State Homœopathic Society in 1895, I quoted a case which to my mind bears out the argument. A woman, pregnant for the first time, showed slight œdema of the hands and feet at three months. No trace of albumin could be found upon repeated examinations up to the fifth month, although the œdematous condition had extended to the face. The patient neglected to present herself for one month. Upon her return, the urine showed a startling amount of albumin; the limbs were enormously distended, nausea and vomiting had returned, and an intense pruritus supervened. I was in favor of a forced delivery, but the patient being then within two weeks of seven months, we determined to wait. The patient, however, miscarried, the child being dead. The placenta was fatty. In six weeks the patient's condition was apparently normal.

Late the same year she conceived again, and the same set of symptoms developed much earlier and with greater rapidity than in the first pregnancy. Again I was induced against my better judgment to wait, but at the fifth month such positive uræmic symptoms had developed that I felt it imperative to relieve the patient, and labor was successfully induced. The symptoms subsided far less rapidly on this occasion than on the first. A careful watch was kept upon the kidneys. The evidences of acute nephritis gradually subsided, but a chronic catarrhal condition remained.

Upon finding herself overdue a few days the following year, she consulted me with regard to an immediate operation, which I refused. She consulted another physician, who urged her to let the pregnancy continue. She submitted, and all but lost her life. In the event of another pregnancy, I should not hesitate one moment. The kidneys have shown most conclusively that they are not able to bear the strain, and why subject them to five or six months' stress, in a vain endeavor to reach the period of viability? It has been my experience in these cases to have the child born dead—the placenta being extensively fatty. When the symptoms do not appear so early in the course of the pregnancy, perhaps not until the seventh month, but persist, I feel that each day adds rather to the danger to the child than increases its chances. More and more of the placenta is cut off from active service by fatty change, until the child dies from lack of nourishment, as happened in a recent case, when again I was persuaded to follow a negative course and wait. I believe that a rapid delivery would have given the child a far better chance at least than it had in the womb of a mother whose inability to nourish it properly was caused by a chronic interstitial nephritis with mitral regurgitation, the chronic condition being intensified by an acute desquamative nephritis. As the nurse remarked, "One can at least do something with a live baby." Here again the placenta was fatty. Seven months had been passed, and the case should have been terminated.

In the induction of labor for the conditions above cited, there are several points to be taken into consideration, and their value carefully weighed and considered. Were the case one of dystocia from bony malformation, and it was found necessary to bring on labor prematurely, any of the simpler methods of starting uterine contractions, such as the use of the continuous hot douche, the tampon, the introduction of a bougie into the cavity of the uterus, or the newer method of injecting glycerin, might answer. The dystocia is not increased by the delay, and the patient will not suffer constitutionally more than is common in the shock of an ordinary labor. If anæsthesia and an instrumental delivery become necessary, there is nothing to hinder such a termination, that is, no special considerations as to heart and kidneys.

But this is not the case when a patient presents herself at any stage of pregnancy and examination reveals organic trouble in the kidneys. Here the pros and cons as to method must be most carefully weighed. Will the patient sustain more damage if the labor is inaugurated by one of the simpler methods, and she is allowed to suffer the delay always incidental to the use of these methods? The pangs of a very long labor are often enough in themselves to determine eclampsia, even when the kidneys have given no evidence of failing powers of elimination until the very last moment. If then for a patient with damaged

kidneys we resort to these slower methods, are we not inviting the very trouble we would avoid? A few hours here may mean life or death. The uterus is unprepared for the work thrown upon it, and only exceptionally responds quickly. If response is too long delayed, anæsthesia and a forced delivery become necessary, in the end adding extra shock to what has already been borne.

On the other hand, if forced delivery is decided upon, an anæsthetic must be used, and the question of its effect on poorly acting kidneys comes to the front. Are we not immediately jeopardizing the mother's life by anæsthesia and the shock of a surgical operation? Which anæsthetic shall be used?

When, however, these questions are well weighed, I think it will be admitted that the safest measure is the rapid forced delivery. The ease with which the patient can be handled under an anæsthetic, the necessity often for version, the absolute assurance of surgical asepsis in an operation requiring from one-half hour to two hours only, the comparative ease with which unlooked-for accidents, as hemorrhage or delayed placental detachment, may be met, added to the fact that the operation may be positively indicated after all other methods have failed—these, I think, surely outweigh the possible danger from anæsthesia especially as we have our choice in that matter.

As to the methods of forcing dilatation, no instrument can be managed with the same intelligence and delicacy as the hand, after the cervix has been sufficiently dilated to render the insertion of even one finger possible. While time is a consideration, I have never found it necessary to dilate with such extreme rapidity as to sacrifice the integrity of the cervical fibres. This is what frequently happens with the branched steel dilators, used forcibly. The insertion of one finger, then two, and so on until the whole hand can be used as a wedge, will answer every purpose. Moreover, I have always been able, with an assistant pushing the uterus well down, to insert one finger of each hand, then two of each hand, thus very much multiplying the stretching force.

One more point: The cervix thus forcibly dilated has a tendency to retract. If instruments are to be applied and the child delivered by the occiput, there is no special danger. Usually, however, to save time, version is performed. Care must be taken in such case that the cervix does not retract before the head is delivered, encircling it and thus causing serious delay. If the cervix is fully paralyzed before extraction is begun, this danger is obviated. A too rapid extraction favors this contraction. Pressure on the head from above, keeping it well flexed, favors easy extraction.

159 West Forty-eighth Street.

---

**Vesico-Visceral Fistulæ.**—Each case must be treated on its own merits, but a few general rules may be laid down: (1) In the first place, any cause of urethral obstruction should be removed, and a direct passage for urine obtained either per urethram by a catheter tied into the canal, or by drainage of the bladder through the perineum. By this means the urine will, in many cases, be prevented from leaking into the fistula, which may then close, or at least be put into a condition capable of cure by subsequent erasion. (2) Any foreign body in or near the bladder, or any other cause of inflammation, should be removed if possible. (3) Abscesses and suppurating cysts in the pelvic cellular tissue must be treated on general principles. (4) All callous fistulous tracts must be laid open and scraped, excised, or cauterized.—Henry Morris.

## THE TOXIC ORIGIN OF CERTAIN NEUROSES AND PSYCHOSES.[1]

By G. W. McCaskey, A.M., M.D.,
Fort Wayne, Ind.,
Professor of Clinical Medicine and Nervous Diseases, Fort Wayne College of Medicine.

The importance of various toxæmic states in the etiology of nervous disease is receiving more attention each year on the part of those who are giving special study to these conditions, and whose aim is to seek for ultimate causes, with reference to the nature and treatment of disease. The fact appears to be that many nervous diseases are immediately produced by toxins of diverse kinds, originating largely in the gastro-intestinal tract and in the metabolic processes of the organism, but that the clinical picture depends quite as much upon hereditary and acquired neuropathic tendencies and environment as upon the precise character of the poisons. The physiological action of the various toxins is of the utmost importance; and it is greatly to be regretted that their isolation, identification, and experimental study are either impossible in the existing state of knowledge, or else, where possible, encumbered by methods which are too burdensome and complicated for clinical purposes. For the present we are obliged, as practical clinicians, to accept evidences of a more general character; less specific, it is true, but still, when taken in conjunction with the clinical picture, quite as conclusive in their bearing as many another clinical phenomenon which we are obliged to interpret as intelligently and reliably as the circumstances will permit.

What are these evidences, and how are they obtained?

In the first place the clinical picture presented will often be, to the experienced clinician, more or less suggestive in character. Vertigo, general pains, headache, general malaise, slight irregular fever, unaccountable periods of feeling of extreme exhaustion, which come and go without assignable cause—these and many other symptoms might be mentioned, some of which are extremely suggestive of auto-infection, and yet may, with the possible exception of the last mentioned, be due to a variety of other causes.

If a neurological study of any given case excludes organic disease and hysteria, then a possibly toxic origin becomes a probability and should be considered; and further it should be regarded as a possible complicating factor in many cases of structural disease, modifying the clinical picture in a marked degree. As I shall not again refer to this phase of the subject I wish here to say that I have seen great amelioration of many incurable organic diseases by the removal of a complicating toxæmia.

The evidences of auto-infection are to be sought for in the urine, the stomach contents, the fæces, and the blood. In the urine the most comprehensive single process is the estimation of the ethereal sulphates. In ordinary states of health about one-tenth of all the sulphates excreted in the urine is combined with aromatic principles mostly of intestinal origin. When this proportion is greatly increased it means a corresponding increase of intestinal putrefaction and resulting absorption. The presence of a considerable quantity of indican, phenol, cresol, or pyrocatechin means the same thing; but an excessive proportion of ethereal sulphates may be found in the absence of a pathological quantity of either of the above-named aromatic principles, combined, of course, with others of unknown character. The presence of acetone or sugar means the presence in the blood of materials toxic to the organism. So likewise does the presence of Gerhardt's iron reaction, which indicates the pre-existence in the blood of a morbid substance resembling

[1] Read before the Indiana State Medical Society, Indianapolis, June 1, 1899.

diacetic acid in some of its reactions, but which I have fully satisfied myself by laboratory experiment is not identical with that substance.

But there is no doubt that these demonstrable urinary products of blood infection fall very far short of covering the ground. There are unquestionably many toxic substances in the blood which do not combine with the sulphates when excreted in the urine, and which, further, cannot be demonstrated by any known chemical method.

In cases, therefore, in which a toxæmia is suspected, and urinary analysis gives negative results, an investigation of the contents of the stomach and colon is desirable and may throw a strong light on the case. In the intestines the presence of large quantities of parasites and protozoa, and of colonies of bacteria to an extent which experience and observation have shown to be pathological, furnishes a sufficient warrant for assigning to this condition an important pathogenic rôle. It is the opinion of competent observers that many of these organisms secrete poisons which are very deleterious to the human body, although this conclusion rests largely upon clinical grounds. In the current volume of "International Clinics" I have reported a case of this sort and quoted numerous observers along the same line. There are many other poisons, besides those comprised in the aromatic group including phenol and indol, with the exact chemical nature of which we are as yet unacquainted.

The stomach should be examined in these cases whenever practicable, whether there are subjective stomach symptoms or not. When the latter are slight and of very long duration, patients will deny their existence, although important conditions may be found upon examination. In a case referred to me by Dr. H. N. Newnam, of South Milfred, and which was fully reported before a recent meeting of the Chicago Medical Society, transient paraplegia and tetany were found to be the result of such an obscure condition, and promptly disappeared upon its removal. In another case referred by Dr. C. L. Ames, of Ada, Ohio, a very chronic neuropsychosis was found to be based upon such a condition, and appropriate treatment was rapidly followed by extraordinary improvement. In this case the ethereal sulphates were greatly increased, phenol and indol being the predominating aromatic principles, but there was also gastrectasia with motor insufficiency and as much as 180 c.c. of nutrient culture medium in the fasting stomach. A very interesting phenomenon in this case was the occurrence of a large quantity of acetone in the urine and a very strong iron reaction coincidently with an acute exacerbation of the symptoms.

So far as the blood examination is concerned, the direct search for toxins is, in the present state of our knowledge, entirely impracticable. Besides this there are other difficulties of a clinical character standing in the way of such examinations. The most that we can do at present is to study the histology of the blood which we know to be materially modified by certain toxins contained in the circulating fluid. A marked leucocytosis and possibly in other cases a leucopenia with modifications in the shapes and sizes of the red cells are perhaps the most important changes to be noted, and, while not at all distinctive in character, help to make up the complete clinical picture which every thorough clinician desires. A careful blood examination should therefore not be omitted in any case of sufficient importance or obscurity to require a comprehensive clinical study.

A slight febrile reaction is present in a certain number of cases of auto-infection, its presence or absence probably depending upon whether the circulating toxins act upon the thermogenic centres or not. In a case of psychoses of intestinal origin, recently referred to me by Dr. L. D. Beyers, of Decatur, an elevation of one-half to one degree was found for several weeks. In another case of several months' duration recently seen in consultation with Dr. J. J. Reynolds, of Defiance, Ohio, the elevation was from one to two degrees.

Indirectly it seems to me quite probable that these auto-infective processes may lead to certain structural alterations of the nervous system, which will later bring the case strictly within the category of organic brain disease. Such a process is not difficult to understand, inasmuch as the vascular changes which undoubtedly result from toxic processes may give rise to nutritional and later inflammatory or even neoplastic changes. A number of cases which clinically corroborate this view have fallen under my observation, in one of which, under the care of Dr. W. K. Mitchel, of Ligonier, Ind., an exceedingly chronic intestinal toxæmia probably led to a localized pachymeningitis.[1]

Many more cases could be cited, bearing in a clinical way upon the problems included in the topic of this paper, if time permitted. The evidences which I have gathered in a somewhat extended clinical study along these lines appear to me entirely conclusive that toxins from various sources may and do give rise to many neuroses and psychoses met with in practice, and I firmly believe that the more these conditions are studied the larger will be the list of cases which find their most plausible explanation in the causes indicated.

I desire, in conclusion, to point out a possible fallacy which I have never for a moment lost sight of and have repeatedly pointed out in published articles—viz., that toxæmic conditions may be the indirect result of nervous disease, as well as the cause of the latter. This is simply another illustration of the so-called vicious circle, which is no new dictum in pathology. It renders more and more complex these clinical problems, and makes it necessary for us to be constantly on our guard in formulating conclusions with reference to the essential pathology of any given case.

### DANGERS OF HEADACHE POWDERS: REPORT OF A CASE, WITH TESTS FOR THE SUSPECTED INGREDIENTS.

By JACOB SOBEL, M.D.,

NEW YORK.

Self-medication has of late assumed such large proportions that, with all the means of procuring various medicaments, the wonder is that so little harm has been done. In fact, considering the reckless sale of dangerous and heroic drugs, and the opportunities of the layman, one is surprised at this moderation in self-damage. This sale of proprietary drugs by pharmacists who ofttimes know as little about the constituents of the given preparation as the patient himself, and the doctor's advice column in the various newspapers, which furnishes prescriptions *ad infinitum* and *ad nauseam* simply upon the patient's diagnosis, without regard for a possible existing contraindication, are the causes in great part of the present evils. Among these, none is more prominent nor worthy of greater consideration than the indiscriminate sale and self-administration of proprietary headache powders, which for the most part contain the anilin synthetics, in who knows what proportions.

[1] This patient was later examined by Dr. H. M. Lyman, of Chicago who agreed with me fully as to etiology, but believed the process to be a sclerosis rather than an inflammation.

It is with the desire of emphasizing the dangerous use of the common anti-neuralgics and febrifuges by persons who are not familiar with their physiological action that the following case is reported:

Miss B——, aged twenty-five years, school-teacher, had been suffering from neuralgia and neurotic headache for some time. This headache had always responded very kindly to one powder of the "Anti-Headache or Half-Hour Headache Healer," which, according to the pamphlet accompanying the box, is guaranteed not to "contain morphine, opium, antipyrin, or other dangerous drugs." The directions given are that, if not relieved by one dose, the powder is to be repeated in half an hour; "in extreme cases three doses may be taken."

On April 7th I was summoned to the patient because "she had taken some headache powders and had suddenly become very blue." My directions over the telephone were to give whiskey, to keep the head low, and to apply hot-water bags and blankets to the extremities. The reply being that whiskey and alcohol in every form would be absolutely refused by the patient, a cup of strong black coffee and half a teaspoonful of aromatic spirits of ammonia were ordered. Upon reaching the patient at 1:30 P.M. I found her in a drowsy condition, with the nose, lips, finger-tips, and toes cyanotic and cold; pulse, 96, somewhat irregular, soft, and small; temperature, 97.6° F.; respirations, 20. The pupils were slightly dilated, reacting to light, and the hands were somewhat clammy. The patient was conscious, and said that her headache, extreme weakness, and chilly sensations troubled her. Soon after my arrival I administered atropine gr. $\frac{1}{150}$ and spiritus ammoniæ aromaticus ℥ ss. per os, and kept the extremities warm.

At 2:15 P.M. the pulse was 96, somewhat stronger; respiration, 20. Spir. ammon. aromat. ℥ ss. was given. At 3:15 P.M. the patient stated that she felt better except for her headache. Pulse, 96; her general condition was much improved, but cyanosis of the lips, finger-tips, and toes was still present, though to a less marked degree. Strychninæ sulphatis gr. $\frac{1}{60}$ was given every four hours, with hot drinks p.r.n. At 8 P.M. the patient felt very much better. The sensation of warmth was returning; the cyanosis of the finger-tips and toes had almost entirely disappeared, but the lips were still slightly cyanotic. Pulse, 84, regular and strong; temperature, 98.2° F. The feet and hands felt warm.

The following morning the patient had a pulse of 72, of good quality, and a temperature of 98.6° F.; respirations, 18. She had slept fairly well during the night. The cyanosis of the lips and extremities had disappeared completely. The patient complained of severe headache, for which the following was prescribed: ℞ Sodii bromidi, ammonii bromidi, āā ℥ ii.; Aquæ menthæ piperitæ q.s. ad ℥ ii. M. S. ℥ i. t.i.d.

On April 9th the patient was up and about, none the worse for her attack.

The following history was then elicited from the patient and her sister, who is a rather accurate observer. At about 12 M. the first powder had been taken without any relief; this was followed in fifteen minutes by another with a negative result. The desired effect not having been attained, she took a third powder within fifteen minutes, and very soon afterward she became cold, drowsy, and noticed that her finger-tips were blue. She took to the couch, thinking that some disease was brewing, and did not in any way associate her condition with the powders. Her lips became blue and her face livid. Nausea or vomiting did not occur. From the history the patient's appearance before my arrival and before the administration of the black coffee and aromatic spirits was far more alarming than the picture as I saw it. At that time her entire face was said to have been intensely blue and her eyes to have had a vacant, distant look. The patient stated that after the third powder "her heart wouldn't beat at all, and then it beat like crazy; once I thought it was beating on the other side."

This history presents, of course, a clear case of poisoning by headache powders, with the following symptoms: Marked cyanosis, prostration, cardiac weakness with irregular heart action, coldness of the extremities, dilated pupils, anxious facial appearance, but complete consciousness.

The next question was, naturally, What is the particular offending ingredient? Two drugs only occurred to my mind, viz., acetanilid and antipyrin. Phenacetin, on account of its expense, did not enter into the consideration. However, to surmise is one thing, to know another; accordingly I took samples of the powder to the Good Samaritan Dispensary, where, with Mr. F. C. Schumacher, I made the following tests: Each powder weighed ten grains, was of a brownish-white color, presented a shining appearance when rubbed on the fingers, and had a sharp, pungent, bitter taste. The appearance and taste were suggestive of acetanilid. When added to water the solution became flocculent, showing the presence of some insoluble substance, perhaps acetanilid, certainly not antipyrin, which is very soluble in water.

A. Tests for antipyrin: (1) To gr. iii. of the powder 10 c.c. of water was added, and then five drops of tinctura ferri chloridi; the solution became slightly colored. In the presence of antipyrin the solution would have turned a bright red. (2) To gr. iii. of the powder 10 c.c. of water was added, and then 2 c.c. of pure spiritus ætheris nitrosi; the solution remained clear. In the presence of antipyrin the solution would have turned dark green, owing to the formation of iso-nitroso-antipyrin. In making this test, I emphasize the use of pure nitrous ether, because otherwise even in the presence of antipyrin the test will fail. This test then is of double value, first in testing the presence of antipyrin, and secondly the purity of the nitre.

Antipyrin having been excluded, acetanilid was tested for as follows:

B. (1) Two grains of the powder were heated with 1 c.c. of a concentrated solution of NaOH and gtt. iii. of chloroform added; an offensive, poisonous odor of phenylisocyanid ($C_6H_5NC$) was given off. This is the iso-nitril test and reacts to acetanilid. On the addition of bromine water the mixture became yellow-red, thus corroborating the presence of acetanilid. (2) Two grains of powder were heated to boiling with 2 c.c. of hydrochloric acid and an equal volume of a saturated watery solution of chlorinated lime added; this gave a turbid red or violet fluid, which turned dark blue on supersaturation with $NH_4OH$ in excess. This is the indo-phenol reaction and speaks for acetanilid. (3) To two grains of the powder 1 c.c. of a sulphuric and chromic acid reagent (chromic acid gr. $\frac{1}{3}$, 10 c.c. of water, gr. xxx. of concentrated sulphuric acid) was added; this gave an intense red color, which immediately turned blue and then faded. This test responds accurately to acetanilid.

Phenacetin was excluded by Mr. Schumacher with the zinc powder and tincture of chloride of iron test.

Thus, whatever other ingredients these powders might have contained, I felt convinced that acetanilid was the disturbing factor and gave rise to the symptoms enumerated. It might be argued that in this instance the prostration and other symptoms were due to an overdose of the powders, and that had the original directions been followed nothing unusual would have occurred. It is, however, this very self-medication, this treatment without regard to idiosyncrasy or the underlying conditions, that is objected to.

All pharmacists under the existing laws have a perfect right to sell headache powders, proprietary or

otherwise. It is highly advisable, however, that they prepare their own powders, know exactly how much of each ingredient they contain, and fortify them (if necessary) with cardiac stimulants such as caffeine, sparteine, monobromate of camphor, etc. No more than three grains of acetanilid should be dispensed in any one powder.

The indiscriminate self-administration of headache remedies composed of powerful aniline synthetics cannot, however, but work infinite harm, unless the public be warned against the great danger which lurks in this method of medication.

## A CASE OF HEREDITARY ARTHRITIS DEFORMANS TERMINATING IN FATAL PERNICIOUS ANÆMIA.

By JOHN S. BILLINGS, Jr., M.D.,
NEW YORK.

Most authorities lay little stress upon the influence of heredity on the disease known as arthritis deformans, and no reports of cases of direct inheritance of the disease have been found by the writer. Writers as a rule limit themselves to the vague statement that "heredity has a certain amount of influence." But by heredity they almost invariably mean a family history of gout, rheumatism, or miscellaneous joint affections. But all consider such influence slight, and Strümpell goes so far as to state that it has none whatever. The general opinion is that a family history of gout can be found for most individuals affected with the disease, and Garrod states that in two hundred and sixteen out of five hundred cases there was a history of some joint affection in the family. No extended search of the literature has been made for cases of arthritis deformans in which the parents of the patients have suffered from the same disease, but no such cases are referred to in the Index Catalogue of the Army Medical Library at Washington. The following case indicates a well-marked tendency to inheritance of the disease:

A. M——, woman, aged forty-seven years, single; seamstress. She was seen August 13, 1898, complaining of pallor, swelling of the feet, and "rheumatism of the hands." There was no history of tuberculosis, cancer, insanity, rheumatism, or gout in the family. Her mother and maternal grandmother had suffered from the same joint affection as herself, viz., a chronic symmetrical enlargement of the carpal and metacarpal joints, coming on late in life, without redness or heat, with little pain or swelling, and answering in all particulars to the description of arthritis deformans. Her maternal grandmother was first affected at the age of forty years. The disease progressed steadily for five years, when it became stationary. No other joints than those above mentioned were affected. She was able to use her hands to a remarkable degree, the patient speaking with pride of some fine needlework done by her grandmother at the age of forty-eight years. She died in her fiftieth year, cause not ascertained. The patient's mother first noticed stiffness of her fingers and wrists at the age of fifty years. There was no pain and but little swelling, with the exception of the small joints. There was no redness or tenderness. The fingers became flexed on the palms and the hands on the forearms. The skin of the hands became smooth and shining. No other joints were ever involved. The disease became stationary at the end of five years. She died thirteen years later of pneumonia. The patient insisted strenuously that her own joint affection corresponded in almost every detail to that of her mother and grandmother.

Past history: The patient was always healthy and strong. There was no history of acute illness. Her menses were regular until one year ago; since when they have been scanty, painless, and very irregular as to the time of occurrence. For the past ten or twelve years she has been subject to periodical attacks of severe dyspepsia with hyperacidity, flatus, and vomiting. There was no history of syphilis. About twelve years ago she first noticed slight swelling and stiffness of the joints of the little finger of the left hand. There was no redness or tenderness. The joints slowly enlarged, became more stiff, and a slight crackling could be elicited on forcibly straightening the finger. She had very little pain. The ring finger of the same hand was next involved, then the little finger of the right hand. The disease progressed slowly until all the carpal and metacarpal joints, with the exception of the left thumb, were involved. At the end of six years the disease came to a stand and made no further progress. No other joints were ever affected.

Present illness: About twelve months ago, for no apparent reason, the patient began to lose flesh and strength. No change took place in the joint affection. Her gastric disorder was giving her little trouble at the time. In fact, she was, and continued to be, less dyspeptic than at any time for the past ten years. Pallor, sallowness, and dyspnœa upon exertion were first noticed about eight months ago. There had been slight œdema of the ankles since the beginning of her illness. This symptom had become very marked within the last six weeks. The patient had fainted several times within the past two months, and had two severe attacks of nosebleed, the last one two weeks ago. She was very nervous. The pallor, dyspnœa, and debility had progressively increased. Her appetite remained good.

Present state: She was sparely nourished, but not emaciated, with marked pallor of the mucous membranes. She had the typical general lemon-yellow jaundice, giving the skin an earthy look. The pulse was twenty-two to the quarter, small in volume, and well sustained, regular in force and rhythm. The vessel walls were apparently normal. The carpal and metacarpal joints of both hands were enlarged and rigid, with the exception of the left thumb, in which the power of motion was fairly well preserved. There were typical Haygarth's nodosities around the joints, which were firmly locked. The fingers of both hands were flexed and carried to the ulnar side. The right hand was flexed upon the wrist and the forefinger carried over the second finger, giving the hand the appearance of a bird's claw, so often described as typical of arthritis deformans. The left hand was in a position midway between flexion and extension. The skin over both hands, and especially over the fingers and finger joints, was thin and shining. The nails were brittle and cracked, and showed signs of old paronychiæ. There were several small subcutaneous nodosities along the sides of the fingers (nodi neuritici; Heberden's nodes). All the other joints of the body were apparently normal. The thorax was well formed; the lungs were clear throughout.

Heart: Apex beat in fifth space in nipple line; punctate. The area of cardiac dulness was normal. The heart sounds were somewhat feeble. There was no accentuation of aortic or pulmonary second sounds. A soft systolic whiff was heard at the apex and faintly at the base; it was not transmitted to the axilla. A very soft venous hum was heard over the veins along the left side of the neck.

Abdomen: There was no apparent enlargement of the liver or of the spleen. The abdominal walls were relaxed. Both kidneys were palpable, the left so readily as to justify its being termed movable. There was slight ascites, and well-marked symmetrical œdema of the lower third of both legs. There was no glandular enlargement.

Urine: Dark brown, clear, no sediment; acid; specific gravity, 1.030. There was a distinct trace of albumin; urea 1.8 per cent.; no sugar; no diazo reaction. The microscope showed a few hyaline casts.

Blood: Red corpuscles 1,344,000 per c.mm.; leucocytes 9,200 per c.mm.; hæmoglobin forty-eight per cent.; hæmoglobin index, 1.9. Stained specimens showed moderate schizo- and poikilocytosis. No nucleated nor polychromatophilic red corpuscles were observed in a large number of specimens. The red corpuscles were intensely stained. A differential count of one thousand leucocytes showed a marked increase in the lymphocytic elements; a so-called lymphæmia. Polynuclears 9.5 per cent., lymphocytes 84.3 per cent., large mononuclears 6.1 per cent., and eosinophiles 0.1 per cent.

The patient was ordered glycerin extract of bone marrow, one drachm three times a day. When seen a week later there was no improvement.

Blood: red corpuscles 1,060,000 per c.mm.; leucocytes 18,000 per c.mm.; hæmoglobin, thirty-nine per cent.; hæmoglobin index, 1.3. Stained specimens were as on previous examination. There were no nucleated red corpuscles. The lymphæmia was more marked. Polynuclears 5.1 per cent., lymphocytes 94.3 per cent., large mononuclears 0.4 per cent., and eosinophiles 0.2 per cent. Prognosis was entered as most unfavorable on account of absence of any attempt at regeneration of red corpuscles.

The patient was not seen again, and it was subsequently learned that she died two weeks later.

The existence of the same disease in three generations of the same family, and all on the maternal side, would seem to be more than a coincidence. The theory that the disease is a trophoneurosis is better supported by the facts than any other. The wasting and hypertrophy which go on side by side, the trophic changes in the skin, so similar to those observed in definite neuro-arthropathies, and finally the well-attested fact that many cases arise during periods of grave mental distress and shock, all lead to the conclusion that arthritis deformans is to be classed among the trophoneuroses. And in no class of diseases is the influence of heredity more strongly marked than in the various neuroses; so that it is not difficult to understand that the condition, conducive to the development of arthritis deformans may, under exceptional circumstances, be transmitted from parent to child. The influence of heredity is difficult to reconcile with the other theories, however, and as the question of the causation of the disease is an open question, the question of its hereditary transmission must be left open also.

Aside from the existence of arthritis deformans in three successive generations, the case is interesting in regard to the severe and fatal anæmia. Several authorities on diseases of the blood have attempted to formulate certain conditions to which the results of the blood examination must conform, in order that a given case may be classed as one of pernicious anæmia. Perhaps the requirement most generally insisted upon is that the blood should contain nucleated red corpuscles; not only the ordinary nucleated red corpuscles (normoblasts), but also the giant nucleated red corpuscles (megaloblasts). These latter are twice the size of the normal red corpuscle, with large, rather palely staining nuclei and polychromatophilic protoplasm.

The other conditions necessarily present to justify a diagnosis of pernicious anæmia are as follows: Marked decrease in the number of the red corpuscles; a relatively slighter decrease in the per cent. of hæmoglobin, so that the hæmoglobin index, or relative amount of hæmoglobin in each red corpuscle, is greater than normal; variations from the normal in shape and size of the red corpuscles (poikilo- and schizocytosis). There is rarely any leucocytosis until the close, but a moderate relative increase in the lymphocytic forms (lymphæmia) is observed in a majority of the cases.

Taking everything into consideration, it is the writer's opinion that the case reported here is to be classed as one of pernicious anæmia, notwithstanding the absence of nucleated red corpuscles in the blood. Such absence points to inactivity of the blood-making organs and is of grave significance. Those interested in this subject are referred to an article by the writer in the *New York Medical Journal* for May 20, 1899.

A third point of interest in connection with the case is the marked lymphæmia. As stated above, a moderate increase in the numerical proportion of the lymphocytes is the rule. But occasionally such increase is very marked, as in the present case. Several cases of terminal lymphæmia of high degree have been reported in pernicious anæmia. The writer, while serving as interne in the Johns Hopkins Hospital, Baltimore, saw such a case, in which, for a few days before death, the leucocytes were 100,000 per c.mm., and of these ninety-nine per cent. were lymphocytes. If such a case was first seen at its close, it would be difficult to determine whether it was one of lymphatic leukæmia with marked anæmia, or pernicious anæmia with terminal lymphæmia.

## REPORT OF TWO CASES OF ACUTE SUPPURATIVE OSTEOMYELITIS.[1]

By G. H. GRANT, M.D.,

RICHMOND, IND.

The infection of a bone that results in acute suppurative osteomyelitis may originate either centrally in the medulla, or externally in the periosteum. In either situation the exciting cause is an invasion of the tissues by one or more of the pyogenic germs: most commonly the staphylococcus aureus. Traumatism and local inflammation and general low-health conditions predispose to the disease, which may be produced in either case not only by the direct absorption of pus-forming germs through an open surface, but also by such germs being carried there from the digestive or respiratory tracts by the blood. Usually, however, the infection has its origin through an external injury or inflammation, and is oftener observed in young growing persons whose bones are highly vascular. The active habits of boys make them more liable to injuries with this disease as a sequel than are girls.

The following histories again illustrate the frequency with which unusual cases occur coincidently in general practice. Both patients were boys of about the same age, both had extensive bone disease following infection from the same slight cause, a "stone bruise," and both were under my care at the same time.

Case I.—June 15, 1898. Henry Roth, aged ten years, inmate of Wernle Orphan's Home, sustained the injury commonly called "stone bruise," while running barefoot. Three days later, the collection of blood becoming painful, he punctured the skin with a hedge-thorn. On June 21st he began to feel sick and to have pain in his left leg, but he did not make his condition known until he was found in bed in the dormitory, late in the afternoon of June 24th, six days after his attempt at amateur surgery. I was at once called to see him, and found him with a temperature of 105.6° F., pulse 130, respiration quick, tongue dry, countenance drawn with pain, left leg flexed at the knee, and a large abscess on the left heel, the site of

[1] Read before the Wayne County (Ind.) Medical Society, January 4, 1899.

the "stone bruise." Not having been informed that the case was surgical, I was obliged to postpone incising the abscess until the morning of the 25th. Under the usual precautions the abscess was evacuated, washed out, and drained with strands of iodoform gauze. At this time the patient complained of great pain in his left knee and in his abdomen. Six hours after the incision the temperature fell three degrees and the pain in the knee abated, but the abdominal tenderness was increasing rapidly; and although the local manifestations steadily improved, a violent peritonitis ensued. Enormous abdominal distention and excruciating pain occurred; the temperature in twenty-four hours rose again to 104° F., respiration was shallow, and the patient seemed about to succumb. These symptoms attained a maximum on July 1st, gradually declining until at 8 P.M., July 4th, the temperature was 100° F. and the pain was endurable. At 7:25 A.M., July 5th, he had a hard rigor; the temperature rose rapidly to 105° F.; he began to expectorate bloody mucus; great dyspnœa and local pain in the right lung appeared; and for the next eight days this enfeebled little boy went through a typical attack of lobar pneumonia. His "critical sweat" occurred July 12th. His temperature fell to 100° F.; the delirium and dyspnœa ceased, but the bloody expectoration persisted several days. As he emerged from his pneumonia he again began to complain of his left knee, the pain becoming intolerable at the inner condyle of the femur. In spite of his great prostration and toxæmia I deemed it unwise to delay free drainage at the point of tenderness, and on July 17th, under full anæsthesia, I incised the tissues and divided the periosteum an inch and a half. Serum and blood only escaped. With the intention of penetrating the bone, if no improvement followed, the incision was kept open with iodoform-gauze strands and the leg was immobilized in a fenestrated plaster splint.

Within twelve hours his temperature fell to normal, the first time since his illness began; and the pain entirely ceased. No bad effects followed the ether, and all indications seemed favorable. On July 31st I removed the splint, and the patient was allowed to be up and to go about on crutches. I received daily telephone reports of continued improvement until August 29th, up to which time he had been considered about recovered by his care-takers. On that date he was seized with a sudden pain in the middle of his left thigh, and on examination his nurse found a swelling, the size of a small egg, on the other side of the middle of the left femur. The following day, when I saw him, the lump had become indistinct, and was surrounded by a boggy fulness. Thus, after nearly a month of apparent improvement, the disease had found a new focus—a treacherous characteristic of this infection. Free incision over the collection allowed the escape of several ounces of milky fluid, the bone beneath being found denuded and partially surrounded by an irregular shell of new bone, forming from the elevated periosteum. The limb was again immobilized, the cavity irrigated daily with hot carbolized solution, and a month was devoted to a vain effort to effect the growth of a shell of bone firm enough to take the place of the sequestrum. But

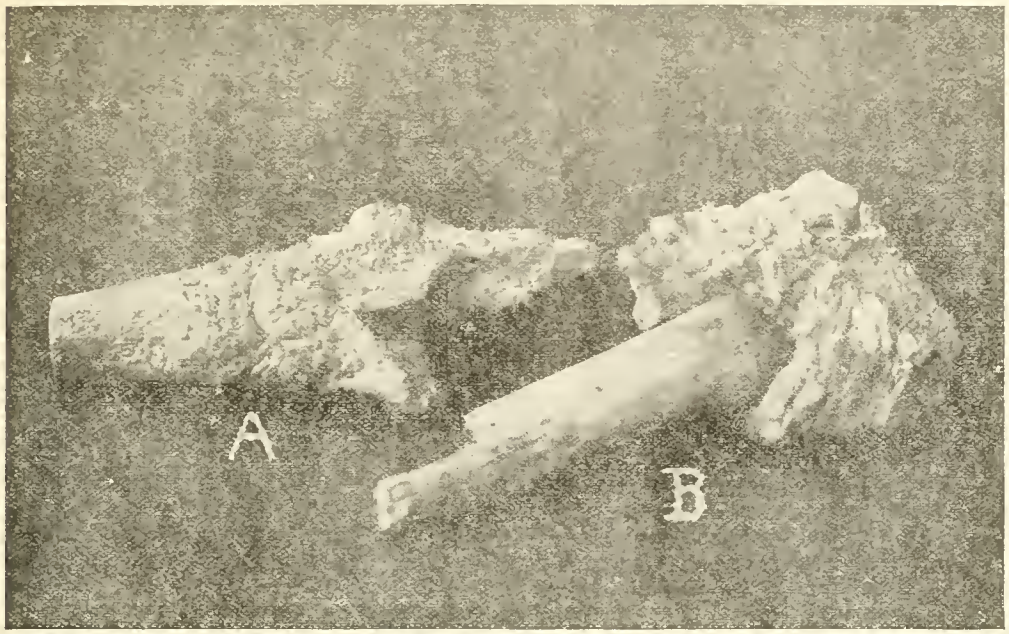

FIG. 1.—A, Upper Fragment of the Femur, showing new bone proliferation; B, Sequestrum within the Lower Shell of New Bone.

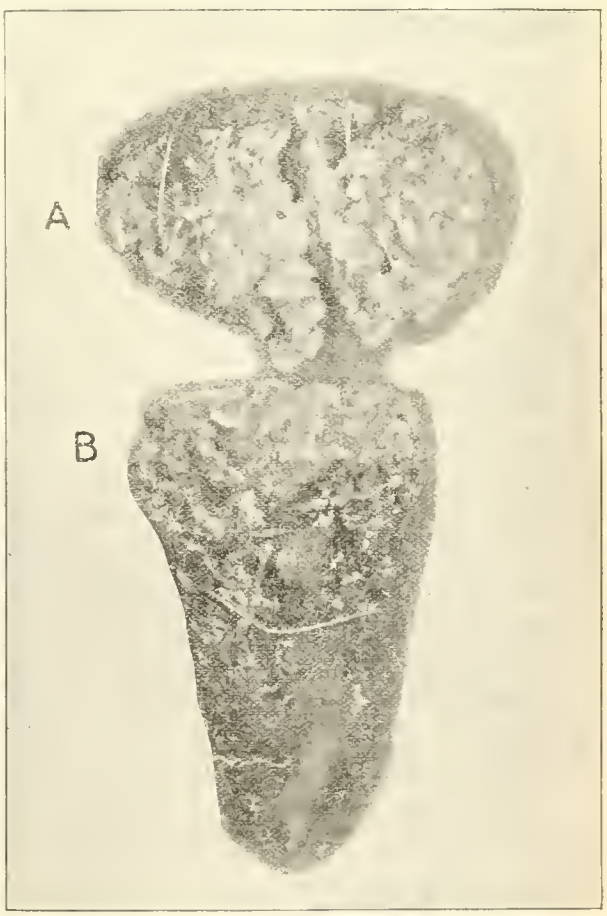

FIG. 2.—A, Upper Articular Surface of the Tibia, in two fragments; B, Fragment of the Shaft.

the patient grew daily more exhausted, having but scant rest day or night, and was rapidly becoming too septic to live long: so I removed him to St. Stephen's Hospital, Richmond, Ind., and on October 11th I amputated his thigh at the upper fourth. He rallied well from the operation. On October 21st he was taken back to the Wernle Home, and is now fat and well.

Case II.—August 23, 1898, I was called to see Luke Smith, aged eight years, who was said to be suffering from "inflammatory rheumatism." He had been sick in bed two weeks, and was feverish, sleepless, in constant pain, which made him alert to guard against every movement of his body or jar of his bed. No physician had seen him within this time, but his parents had gotten medicine for him on their own diagnosis until his condition grew so alarming that a change of plan was evidently imperative, and I was asked to examine him. His temperature was found to be 104° F., pulse quick and weak, skin deeply pigmented and dusky, and the face wearing a senile look of anxiety and anguish. The calf of his left leg and his left knee were red, swollen, and boggy, and a large abscess had formed on the buttock of the opposite side. I had never seen this patient before, and no thought had been entertained by his parents that any injury had occurred to him; but with my other case in my mind I ventured the opinion that he had had a "stone bruise," and asked how long ago he had "opened" it. At first no such circumstance was recalled, but at length the patient volunteered the interesting information that he had a painful "stone bruise" while barefoot four weeks previous, and that he had released the collection of blood by tearing it open with his finger-nails. Examination of his left foot showed a large, partially healed sore at the head of the first metatarsal bone, on the sole of his foot. After opening the abscess on the right buttock I made a free incision inside the crest of the left tibia, and demonstrated to the parents that his "rheumatism" was really a large, bad-smelling collection of pus. A counter-opening was made along the outer border of the quadriceps tendon, liberating more pus, and facilitating drainage. Previous to the time this little patient tore open the "stone bruise" he was in perfect health, but following that incident he said his foot became very sore, and stayed so until his "rheumatism" got so bad he forgot the foot. Through the lower incision the tibia was found denuded, and gave the "sand-stone" feeling as far as it could be reached. The day following this operation the temperature fell to 100° F., but the pain and apprehensiveness remained. Consent was not obtained to the removal of the dead bone until October 3d, at which time I took him to St. Stephen's Hospital, and operated on him one week previous to the case first detailed. The tibia was so completely disorganized that the head was removed in two pieces by my fingers, and the larger fragment, the shaft, broke off from the sound portion while being manipulated in examination. All the rest of the necrosed tissue I removed by chiselling; the knee-joint and large cavity remaining were thoroughly irrigated with a hot bichloride solution, 1:4,500, the wound packed with iodoform gauze, and the patient put to bed, where he made an uneventful recovery, being removed to his home ten days after operation. He is now very active, fat, and well, getting about town on crutches; the fibula is enlarging, and with the aid of some local support I believe he can eventually walk without a crutch. It is of interest to note the fearful rapidity of the destruction of bone in this latter case. I first saw him about four weeks from his original injury, and yet it was apparent that his tibia had been necrosed throughout its upper third for some time.

Few surgical conditions show more prompt and gratifying improvement than do these of infective bone disease after the dead and infective tissue is removed. Not only is this true in acute infection, but in tuberculous as well. The unfortunate feature about them is, that they seldom come under a surgeon's care until the tissues are extensively destroyed.

## Progress of Medical Science.

**Asthma.** — Dr. Sidney Martin (*Deutsche Medizinal-Zeitung*, July 27th) says: "Spasmodic asthma is a nervous affection and occurs primarily as well as secondarily. The typical, uncomplicated attack, such as is seen in adults and children, occurs suddenly in the early morning hours, between two and four o'clock, in the form of intense dyspnœa, the patient of necessity catching a chair or the bed in order more readily to bring into action the accessory respiratory muscles. The cardinal symptoms of the asthmatic attack are embarrassed circulation, diminution of the oxygen supply, and absence or marked diminution of air to the lungs; these symptoms last a variable length of time and run their course with cough and mucous expectoration. The etiology of the different attacks is various and for the most part vague. Hay asthma is a form of the disease which is directly traceable to the inhalation of the pollen of plants and flowers. Again asthma may precede indigestion, or the latter may cause an asthmatic attack, the so-called peptic asthma. Asthmatic attacks also follow pulmonary affections. Bronchitis too may cause asthma (bronchitic asthma), as may diseases of the nose and throat. In some instances (summer asthma) the attack occurs for years during the summer months, disappearing in October or November, only to return again the following year. Many theories have been advanced in explanation of the asthmatic attacks. The assumption of an acute inflammation of the bronchi might well be dropped, since asthma is neither a febrile nor an infectious disease. Another theory has it that the attack is due to an acute swelling of the bronchial mucous membrane. The most acceptable theory is that the attack is due to a spasm of the bronchi, during which the smooth muscles of the smaller bronchi are firmly contracted, thus rendering the entrance of air into the lung exceedingly difficult. As far as treatment is concerned, the first indication is to relieve the attack. In uncomplicated cases subcutaneous injections of morphine, and chloral or chloroform inhalations relieve the attack. The continuation of such medication, however, is to be deprecated, and such treatment is to be undertaken by the physician only. The inhalation of the smoke from burning nitre paper or prepared cigarettes and powders is the popular remedy, and gives relief in many instances. The powder contains stramonium and nitrate of potassium; the cigarettes, tobacco and stramonium. At times pills containing 0.03 of morphine and 0.002 of atropine, given before bedtime, are very efficacious. In place of atropine, extract of stramonium might be used. Furthermore, it becomes necessary to prevent recurrences, since they lead to bronchitis and emphysema. Very frequently, in patients who have many attacks, iodide of potassium and arsenic are used. The iodides may be combined with stramonium. Unfortunately, stramonium, if pushed to the limit, produces a paralysis of accommodation, especially in nervous individuals. Arsenic in the form of Fowler's solution is a very useful drug in the continuous treatment, and may be combined with iodide of potassium. Local

conditions also require attention. The insufflation of solution of sodium bicarbonate or sodium chloride is very useful in instances in which there is a nasal hypersecretion, *e.g.*, hay asthma. An application of cocaine to the nasal mucous membrane, as well as cauterization, relieves the attack at times. The regulation of diet is of the utmost importance. Meals must consist of easily assimilated substances, which must be taken in moderate quantities. By these means, combined with alkalies after meals, the attacks of peptic asthma are very much ameliorated. In many cases in which other drugs have failed, cod-liver oil produces brilliant results. If the above line of treatment is followed, asthma in children will be readily cured; on the other hand, the condition of adults who have had many attacks will only be benefited; and, finally, in some cases the treatment, as in epilepsy, seems to be useless."

**The Urine in Chronic Disease.**—Dr. Boardman Reed (*International Medical Magazine*, July, 1899) states that "the urine should be examined most carefully in every case of chronic disease, with few exceptions, from infancy to old age, and when it is one of unusual importance, or much obscurity, many more tests should be made than are customary. Next after the tests for albumin and sugar, perhaps the most necessary one is that for indican, and it is very easily and quickly made. That for the aromatic sulphates is no less important, but is more difficult. Either indican or aromatic sulphates in large excess must raise a strong suspicion of intestinal disease. The total amount of solids passed in twenty-four hours is roughly ascertained by a very simple calculation, and affords valuable knowledge as to the renal adequacy. Another unusual test that furnishes most useful and, I may even say, indispensable information in all cases of malnutrition, whatever the age of the patient, is that for the total acidity—the total amount of acid elements of all kinds, free and combined as salts. This will be found to vary in neutralizing power in adults all the way from the equivalents of 5 or 10 c.c. to 70 or 80 c.c. of the one-tenth normal solution of caustic soda in each 100 c.c. of urine. A very low percentage of acids is frequently seen as a result of over-medication with alkaline drugs or the stronger alkaline waters. A high acidity, on the other hand, is very often found in consequence of much fermentation in the stomach or intestines. It is usually present before the development of rheumatism, and its persistence threatens danger to the system generally through a too great diminution of the alkalinity of the blood. A determination of the amount of uric acid in the urine of twenty-four hours frequently affords the key which unlocks a difficult problem. It is scarcely necessary to remind an association of physicians, at this day, that a microscopic examination of the urine is in most cases quite as necessary as the usual chemical analysis, if we would learn the whole lesson that this most important of the excretions can teach us. Even in the absence of albumin, hyaline casts are danger signals at least, while epithelial and granular casts are usually an evidence of serious structural lesions. A gonorrhœa cannot be certainly differentiated from other purulent urethral discharges except by the gonococci, and tuberculosis of the genito-urinary tract is often revealed by finding the bacilli in the urine. Spermatorrhœa, though not so common or deadly as the quacks pretend, is a real disease which is often overlooked, and cannot be demonstrated without the help of the microscope."

**Early Signs of Phthisis.**—Dr. John W. Moore (*Medical Standard*, July, 1899) says of the relative values—diagnostic and prognostic—of certain signs and symptoms which herald the onset of pulmonary consumption: "The so-called 'tuberculous red line' along the gums may mean much or little. Its absence encourages; its presence, on the other hand, may be due to other causes than tuberculosis. I have seen it in the neighborhood of carious teeth, or where "tartar" incrusts the crown of a tooth. Its diagnostic value is thus qualified. Clubbed finger-tips are common to phthisis with many other wasting diseases or conditions which interfere with nutrition, such as valvular or other heart affections. Morning sickness and want of appetite for breakfast are common forerunners of consumption. To the same category belongs distaste for fatty foods and capricious appetite. Myotatic irritability of the pectoral muscles and of the platysma myoides is a valuable sign. So also is tenderness on pressure over an apex of a lung which is the seat of commencing tuberculous deposition. Interrupted inspiration (jerking, or cog-wheel, inspiration) is a sign of doubtful value. It is so often present in nervous youths or in nervous and chlorotic girls that its diagnostic importance is largely discounted. Among the earliest physical signs of phthisis we should include lessened movement of the chest wall (expansion), an abnormally clear percussion note, deficient vesicular breathing, relative or absolute intensity of the heart sounds over the affected apex, and relative or absolute intensity of the pulmonary second sound."

**Kolpotomy for the Removal of the Adnexa.**—Dr. Raczinski (*Deutsche Medizinal-Zeitung*, August 10, 1899) says that the advantages of the vaginal method of extirpation over laparotomy are as follows: (1) The patients consent more willingly to the operation, and at the same time it is possible to remove the smaller and harmless new growths, without waiting until the growths become unbearable on account of their dimensions, or until inflammatory adhesions, suppuration, or malignant degeneration occur. (2) Diminished chances of infection from the air, the hair, beard, mouth, and nose of the operator. (3) The possibility of operating under poorer conditions. (4) Diminished mechanical irritation of the intestines and parietal peritoneum by the hands of the operator and his assistants, sponges, instruments, sheets, etc., which come in direct contact with the abdominal cavity. (5) Diminished danger in cases of flow of the purulent contents from the torn sac of the new growth. (6) More satisfactory post-operative course of the case and speedy convalescence. (7) Absence of danger of ventral hernia. (8) No need of wearing an abdominal binder. (9) The possibility soon after the operation of doing bodily work. (10) Diminished mortality.

**Life Prolonged for Two Hundred and Forty-Three Days as the Result of Saline Transfusion in a Case of Diabetic Coma.**—Oliver reports the case of a coal miner, thirty years old, who came under observation first suffering from diabetes of eight months' duration. He had developed rather rapidly polydipsia and polyuria. In a few months he had lost fifty-six pounds in weight. The urine contained a large amount of sugar. The knee-jerks were absent. There had been gradual loss of strength, and emaciation had been progressing rapidly. After treatment with codeine and dieting, the patient was so much improved that he undertook to go home, a distance of fourteen miles, by rail. Later in the day he was found in a state of deep unconsciousness in a railway carriage on an entirely different line from that by which he should have travelled. He was at once transfused with two and a half pints of saline solution (one drachm of sodium chloride to one pint of boiled distilled water, allowed to cool to 112° F.), the fluid being permitted to pass slowly into the right median

basilic vein. A purge was also administered. By degrees consciousness was regained. For the first day or two after the transfusion only a small amount of urine (twenty-one ounces) was passed free from albumin and acetone, but rich in sugar. In a few days after this the daily discharge of urine was one hundred and ninety ounces. At this time the patient's skin, especially that of the hands, was much bronzed. For some time afterward the patient kept remarkably well for a diabetic. He was unable to return to his former heavy work, but on the whole life was fairly enjoyable. The disease, however, gradually progressed to a fatal termination, death taking place in coma two hundred and forty-three days after the operation of transfusion.—*The Lancet*, August 26, 1899.

**Fatal Acute Alcoholic Intoxication in a Child.**—Dr. Walker reports, in the *New York Medical Journal* of August 19th, the case of a boy six and one-quarter years old, who obtained surreptitiously and drank about three ounces of whiskey. Shortly afterward, while at breakfast, the child first dropped a plate and then fell from his chair. A little later he fell asleep on the floor, and he was put to bed. The child continued soporose for nine hours, when the pupils were found equal, dilated, and unresponsive to light; the internal and superior recti were contracted; the conjunctivæ were insensitive. The pulse was 145, small, weak, and compressible, but regular. The respiration was 40, easy and quiet. The skin of the head and face was cool and slightly moist. The tongue and lips were somewhat dry. The trunk and the extremities were hot and dry. The axillary temperature was 103.2° F. In spite of all remedial measures there was slow but continual failure of heart and respiration. After the lapse of three hours more a severe clonic convulsion occurred, lasting perhaps ten minutes, and from this time there were almost constantly recurring localized spasms of the muscles of the face and extremities; the left side being affected much more than the right. Occasional nystagmus was present. Cheyne-Stokes respiration set in four hours later, and death from cardiac failure took place about twenty hours after ingestion of the whiskey. The rectal temperature rose to 105.3° F. just before death.

**A Simplification of the Phenylhydrazin Test for Sugar in the Urine.**—By reason of the length of time necessary and the complications of the process, the usually advised method of testing for sugar in the urine by means of phenylhydrazin has not been widely accepted. Karewski, in the *Berlin. klin. Wochenschrift*, 1899, No. 19, suggests a simpler procedure. Five drops of pure phenylhydrazin are added to ten drops of glacial acetic acid, and to this 1 c.c. of saturated salt solution. To this white cheesy mass, 3 c.c. of urine is added and the whole boiled in the test tube for three minutes. After cooling for some time the presence of sugar can be detected by means of a macroscopic yellowish precipitate, if the sugar is present in greater quantities than 0.5 per cent.

**The Influence of Antitoxin on Diphtheric Paralysis.**—As the result of observations made at the Eastern Fever Hospital of the London Metropolitan Asylum's board at Homeston, Woollacott (*The Lancet*, August 26, 1899) presents the following summary of the influence of antitoxin on diphtheric paralysis: Up to the present the percentage has increased on the whole. There is some evidence that large doses, *i.e.*, not less than four thousand units, of antitoxin are more effective than small ones, both in preventing paralysis and in diminishing the mortality due thereto. The earlier antitoxin is given in diphtheria, the less likely is paralysis to follow. Should it occur after early injection, it will probably be mild, and of comparatively short duration. The type of paralysis has, on the whole, become less severe, or, at all events, less dangerous to life. Finally, diphtheric paralysis has become more prone to attack the young. This change in age incidence has possibly made some minor differences in the relative frequency with which the various forms of paralysis are observed. The practical conclusion is that the full value of antitoxin is obtained only by using it early and in efficient doses. If this is done, not only is life saved, but tedious complications are prevented, or at least deprived of their dangerous characters.

**Successful Nephrectomy for Sarcoma of the Kidney in an Infant.**—Dr. Robert Abbe reports in the *Annals of Surgery*, vol. xxx., No. 3, 1899, the case of a girl infant who at birth was observed to have a tumor in the right side of the abdomen, which continued to increase with its growth. The chance of survival appeared so slight that it was decided to attempt the operation of removal at the age of one month. A slight gain in the child's weight at this time, however, led to a postponement. At the age of three months the growth of the tumor was found to have been parallel with the child's growth, but it did not seem as if the child had vitality enough to endure the necessary surgery, so that delay for a few months was advised. Under closest scrutiny of the child's health and nutrition during the interval, the weight increased five pounds. When the child was eight months old, it presented a wrinkled and old appearance, and the tumor filled three-quarters of the distended abdomen. It sprang from the left loin and crowded the colon far to the right of the median line. The condition of the patient seemed now to justify operation, and the following extra precautions were observed, and it is thought they conduced largely to success in so frail a subject: (1) A specially warm room for operation; (2) a heavy ironing board thickly padded with blanket and sheet and kept hot until the child was secured to it by bandages, so that it could be raised to a Trendelenburg position; (3) all of the extremities were well enveloped in cotton and flannel, and the remaining parts of the uncovered chest and abdomen were constantly warmed during the operation by relays of steamed towels. Care in sacrificing as little blood as possible resulted in the loss of not more than an ounce during the operation. Through a median incision above the naval to introduce two fingers the peritoneum was found pushed to the right. A transverse incision through the left half of the abdomen from the navel to the lumbar muscles gave free access to the growth, which could be separated from the abdominal wall by blunt dissection. The colon was spread out upon the median and upper aspect of the growth. Much care during its separation had to be exercised in order to preserve its nutrient vessels. The vascular pedicle of the large growth was at last isolated, separated from the ureter, and tied with catgut. The ureter was cut off close to the bladder; the abdominal wound was closed in tiers, buried silkworm-gut interrupted sutures being applied at points essential for strength, and continuous catgut sutures for other layers. The post-operative course was one of uninterrupted convalescence. The remaining kidney gradually increased its function, until within ten days it was secreting much more than normal for both. The child quickly gained color and flesh (six and one-half pounds in three months, and became as fine in health and activity as its two well sisters. The removal of the tumor seemed to be clean and complete, the enucleation from its cellular bed being perfectly satisfactory. No infected gland or extension of disease was encountered. The opposite kidney was normal on palpation. On histological examination the tumor proved to be a pure spindle-cell sarcoma.

New York, September 30, 1899.

## THE DIFFERENTIAL DIAGNOSIS OF APPENDICITIS.

A TYPICAL case of appendicitis occasions no difficulty in diagnosis; not so, however, with aberrant cases. There are few abdominal and even pelvic conditions that appendicitis may not sometimes simulate, and there are no pathognomonic signs. The disease may pursue an entirely latent course and be unattended with obtrusive or characteristic symptoms, or it may not come under observation until peritonitis has developed. Sometimes the nature of the disease is masked by the administration of opium. A knowledge, therefore, of the conditions with which appendicitis may be confounded will often prove most useful. A number of interesting cases illustrating some of the difficulties in diagnosis have recently been reported by Mühsam in the *Berliner klinische Wochenschrift* for July 31, 1899. In one of these the decision lay between appendicitis, pancreatic hemorrhage, and perforated gastric ulcer; the autopsy disclosed a perforated duodenal ulcer close to the pylorus. In the case of a boy, five years of age, a fatal ileo-colic intussusception was mistaken for appendicitis. In another case in which appendicitis was first diagnosticated, and perforated typhoid ulcer subsequently, the latter condition was found upon post-mortem examination. A diagnosis of appendicitis was made in two cases in which, upon operation, peritonitis following perforation of a gastric ulcer, with abscess formation in the ileo-cæcal region, was found. Carcinoma of the cæcum has been mistaken for appendicitis, but in one case of carcinomatous stenosis of the sigmoid flexure reference of the pain to the ileo-colic region and a sense of resistance in this situation led to a diagnosis of appendicitis, the error being disclosed upon operation. In one case of fecal abscess from perforation of the bowel by a pin that had been swallowed, a diagnosis of appendicitis with adnexal disease had been made. It is important in the diagnosis of appendicitis to secure a careful history of the beginning of the trouble, and especially to know whether gastric symptoms were present earlier or at the beginning. Pain radiating to the shoulder is suggestive of disease of the liver; if associated with signs of perforative peritonitis the possibility of duodenal ulcer must be borne in mind. Pain in the right hypochondrium is said to be more characteristic of this condition, and pain in the left hypochondrium more characteristic of gastric ulceration. Intussusception may be recognized from the history and the occurrence of characteristic bloody stools, together with the presence of a tumor in the abdomen or at the anus. A diagnosis of typhoid fever may be arrived at from the general condition, and from examination of the blood, of the fæces, and of the urine. Fecal abscess resulting after the swallowing of needles or pins, or peritonitis, especially with pain in the right iliac region after stricture of the bowel, may elude accurate diagnosis.

## THE PROBLEM OF THE TROPICS.

IF we are to "take up the white man's burden" with any degree of success, our soldiers and emigrants from this country to tropical regions must first learn how to live in health under their new conditions. American medical men, too, should seize every opportunity to become versed in the etiology, diagnosis, and treatment of the tropical diseases. The question of the ability of the white man to acclimatize himself in the tropics is one that has been fully discussed in medical journals in all parts of the world within the past few years. Opinions differ widely on the subject. Pessimists say that it is impossible. For example, Mr. Benjamin Kidd, who is regarded by some as an authority on matters connected with the tropics, speaks as follows: "The attempt to acclimatize the white man in the tropics must be recognized to be a blunder of the first magnitude. All experiments based upon the idea are mere idle and empty enterprises foredoomed to failure. Excepting only the deportation of the African races under the institution of slavery, probably no other idea which has held the mind of our civilization during the last three hundred years has led to so much physical or moral suffering, and has strewn the world with the wreck of so many gigantic enterprises." However, Mr. Kidd expresses the opinion only of the minority, and such authorities as Manson, Sambon, and Cantlie hold that under certain conditions the white race is eminently fitted to cope with the dangers and difficulties of tropical life. The last issue of the *British Quarterly Review* contains an article founded upon the recent writings of some experts best qualified to speak judicially on the subject, and it is to be remarked that they, one and all, give views diametrically opposed to those of Mr. Kidd and the pessimists. Of course there is no evading the fact that in bygone days the mortality was fearful, but that it is not so now, when ordinary care is exercised, is easy to demonstrate. The *British Quarterly* says: "It must be borne in mind that the conditions of civilization in former years have greatly changed. Improved sanitation has reduced mortality to an enormous extent. In India the annual mortality of European troops prior to 1859 stood at 69 per 1,000, now it has fallen as low as 12 per 1,000. Colonies which were once called the European's grave, such as the West Indies, Hong Kong, and Algeria, are now

recommended as health resorts. The real obstacles to the colonization of tropical lands are not temperature and moisture, but living organisms. Aboriginal man, wild animals, poisonous snakes may be serious obstacles to a foreign invasion, and many an attempt at conquest has been frustrated by such opponents; but the most fearful foes are the minute pathogenic organisms, or, in other words, the diseases peculiar to each region. These are sometimes amazingly fatal. These organisms have their especial geographical distribution, just like other animals and plants which do not become parasites of man. Some diseases like malaria and dysentery have a very wide distribution; others, like endemic hæmaturia, sleeping-sickness, and verruga, have very narrow limits; others again, like cholera and yellow fever, have restricted endemic areas, but under favorable conditions may become widely diffused in great epidemics. They are all intimately associated with other forms of life, and their limitation and diffusion are therefore dependent on the limitation and diffusion of other plants and other animals." If we are to accept Manson's theory in regard to the connection between malaria and a certain species of mosquitos, then the distribution and prevalence of malaria are due to the distribution of these mosquitos; and the dissemination of plague is probably owing to its prevalence among, and conveyance to man by rats. To revert, however, to the question of the white man's ability to live in health in tropical lands, it must be said that a certain period of time is required for a newcomer to adapt himself to climate and environment and thus to acquire a degree of immunity. Again by some it is urged that if a white person wishes to retain his good health in the tropics it is absolutely essential that the strictest attention be paid to diet and clothing. On this point the *British Quarterly* has this to say: "The general opinion is that a vegetarian diet is better suited to a tropical climate, and that the use of alcohol is to be entirely prohibited. We cannot agree altogether with these statements. The eminently carnivorous Anglo-Saxon would be very unwise if he radically modified his diet on first landing in a tropical colony, and alcohol is not more deadly in the tropics than in any other climate."

Perhaps this expression of opinion will not meet with universal approval. Although it might be unwise for a European to alter the nature of his food at once, still there can be no doubt that less meat is required in a hot than in a temperate or cold climate, and it is just as certain that the less spirits consumed by the Caucasian in the tropics the better it will be for his health. The marvellous decrease in mortality among Europeans resident in tropical lands has been almost wholly effected by improved sanitation, and this fact goes to show that the diseases of the tropics can be as successfully fought as those of the temperate zone. What is now required is a more intelligent method of probing the secret of these diseases, and a more accurate understanding of the means by which they are conveyed to man. As we pointed out in the MEDICAL RECORD some years ago, it would be well—in view of the work to be done in the West Indies and the Philippines—if a number of schools for the teaching and investigation of tropical diseases were established in this country.

## DIABETES IN CHILDHOOD.

SUGAR may appear in the urine under various conditions, but only its persistent presence is indicative of the existence of diabetes. The latter likewise is of varied origin and must be considered finally as a permanent derangement of metabolic equilibrium. The disease, though not rare in children, is not at all common early in life. The prognosis seems to vary almost directly with the age of the patient, the disease appearing to acquire special virulence, pursuing a rapid course, and invariably terminating in death in childhood, while after the middle period of life, and particularly late in life, it often pursues a relatively benign and indolent course, and is not responsible for death; although, when it is once firmly established, recovery is rare. An interesting case of diabetes in a child is reported by Sequeira in *The Lancet* for July 15, 1899, in which the sugar almost totally disappeared in the course of an attack of catarrhal jaundice, although it remained unchanged during an attack of measles. The patient was a child, three years and two months old, who, following an attack of influenza six months previously, had complained of excessive thirst, had passed large quantities of urine, and had lost flesh. The most prominent symptom, however, was constipation. Prolapse of the rectum had developed in consequence of a fissure of the anus, it was thought, and stretching of the sphincter had been practised. Examination of the urine disclosed the presence of a large amount of sugar. No history of diabetes in any other member of the family could be elicited. The patient presented a bright malar flush, clear conjunctivæ, and dry and almost vermilion-red lips; the surface of the tongue was dry, glazed, and beefy in appearance; and the skin was harsh and dry. The muscles of the limbs were flabby, but there was generally a fair covering of subcutaneous fat. The edge of the liver was palpable one finger's breadth below the costal margin. For a week no restriction was placed upon the diet. During this period as much as 2,500 c.c. of urine with a specific gravity of 1.040, and containing eleven per cent. of sugar, were passed in twenty-four hours. At the end of this time the diet was partially restricted, and some amelioration in the symptoms took place. After nine days a strictly diabetic diet was instituted, and the effect was remarkable. The patient became quite comfortable, and ate, drank, and slept well. The intense thirst diminished, the quantity of urine fell at once to 1,000 c.c. in twenty-four hours, and in a few days to between 500 and 600 c.c., while the sugar fell to four per cent. Subsequently, however, the amount of urine and the proportion of sugar again increased. Improvement then followed upon administration of Fowler's solution of arsenic in doses of two minims thrice daily. In the further progress of the case jaundice developed, with elevation of temperature and enlargement of the liver, while the amount of urine fell to between 635 and 775 c.c., the specific gravity

to 1.016, and the proportion of sugar to 0.7 per cent. The former condition of affairs, however, soon became re-established. Subsequently the child passed through an attack of diphtheria, but without noteworthy reduction in the glycosuria. Soon after this acetonuria developed and was followed by sopor, coma, and death. Upon post-mortem examination no gross change was appreciable in the pancreas; the kidneys were in a state of cloudy swelling; the wall of the urinary bladder was hypertrophied; the liver and the bile-ducts exhibited no abnormity.

---

## ANIMALS AS DISSEMINATORS OF THE PLAGUE

When the plague reached Egypt and the African shores of the Mediterranean, fears were expressed that the epidemic might once again invade the continent of Europe. These prognostications have unfortunately been fulfilled. How or by what means this malady is spread remains as yet an unsolved problem. However, this much is known, that rats are peculiarly liable to the infection, and in India and China it has also been shown that by the agency of these vermin plague has been conveyed from district to district. That bubonic plague affects rats and through them spreads among men may then be regarded as a fact which has been demonstrated in a sufficiently conclusive manner. Wherever plague has occurred among human beings it has almost invariably been preceded by an epidemic among the rats. It has likewise been observed that the interval between two outbreaks of the plague seems to be about the time required to renew the rat population, which is always decimated by the virulence of the infection. It is possible, therefore, that rats have played an important part in the introduction of the disease into Portugal.

But rats are not the only animals prone to infection by the plague germs. Some few months ago Dr. Alice Corthom, on plague duty in Bombay, had her attention called to the fact that several monkeys had been observed to drop dead from the trees. Some of the bodies were procured, and upon dissection were found to present all the signs of plague, and the correctness of these investigations was confirmed by subsequent examinations at the plague research laboratory in Bombay. Squirrels also which died suddenly were examined with a like result. *The Lancet*, commenting upon this new phase of the matter, says that "the importance of the fact that monkeys and squirrels are also susceptible to plague infection cannot be overestimated, especially in relation to the carrying of infection from one district or village to another."

Although it would appear that this country has, for the present at least, but an indirect interest in the plague question, the fact should be borne in mind that a widespread epidemic in Europe must needs have a disastrous effect on the commerce of the world at large. And the possibility of the introduction of the disease in this country through the instrumentality of rats in ships coming from infected ports should be borne in mind, and doubtless is, by sanitary officers.

## YELLOW FEVER—A CONTRAST.

A report from Havana recently received in Washington states that the number of deaths from yellow fever in that city last month was far less than during any August in the last ten years. In August of every year, from 1889 to 1898, the number of fatalities from yellow fever was from six to twenty-six times as many as in August, 1899, when only ten deaths occurred. The improved condition is due, of course, to the better system of sanitation introduced by the United States authorities. In the mean while there are thirty or more new cases of yellow fever reported in Key West every day, and the statement is made that nothing can be done, and "the fever must run its course"!

There is a moral in this contrast which we hope will not be lost sight of when new sanitary legislation is proposed during the next session of Congress. It surely ought to be no more difficult to stamp out or repress yellow fever in Key West than it is in such pest-holes as Havana and Santiago were under Spanish rule. But in the latter the authorities can establish regulations and see that they are enforced, while in Key West the municipal authorities, the State authorities, the military authorities, and heaven knows how many other authorities must consent before the orders of the Marine Hospital officers can be executed, if they can be executed at all. If Key West were attacked by a material foe, martial law would be proclaimed, and the municipal authorities, and the State authorities, and all the other authorities would for the time being have nothing to say in opposition to the supreme military authority. There ought to be equal power granted to the national sanitary authority to compel obedience when the city is attacked by a microbic foe. The casualties inflicted by the army of Gen. Juan Amarillo are vastly greater than those that the soldiers of Gen. Ramon Blanco could have caused had they been able to make a dash across the water from Havana last year. Yet no determined resistance can be made, and "the fever must run its course."

There should be a central health authority for this country, a department, or at least a bureau, of public health, and in time of epidemic invasion the head of this department or bureau should have the power to enforce his decrees against the opposition of local health boards or commercial bodies. We cannot doubt that, had the Surgeon-General of the Marine Hospital service that power now, the fever at Key West would run its course in very short order.

---

**An Insulting Suggestion.**—The proprietor of a sanatorium near this city is sending to the physicians of New York an advertising circular accompanied with the following letter:

"Dear Doctor: The inclosed circular will emphasize the fact that I am giving especial attention to its subject-matter at the sanitarium. For each and all you send, or who come through your recommendation you will be entitled to a check of $15, and I am certain will also win the sincere gratitude of the patient."

## News of the Week.

**The Idaho State Medical Society.** — The seventh annual meeting of this society will be held at Lewiston, Idaho, October 5 and 6, 1899, under the presidency of Dr. C. W. Shaff, of Lewiston. The secretary and treasurer is Dr. Ed. E. Maxey, of Caldwell.

**The South African Medical Congress,** which was to have been held in Cape Town during this month, has been postponed to September, 1900, the unrest caused by the war scare having threatened to keep away many practitioners living in the country districts and beyond the borders of Cape Colony.

**A Doctor Decorated.**—Dr. A. Rose, of this city, writes: "Allow me the pleasure to inform you that His Majesty George I., King of the Hellenes, by decree of August 13th, A.C., has conferred to me the Silver Cross of the Knights of the Royal Order of the Saviour. This high distinction I owe to my modest labors, the first of which were published in the MEDICAL RECORD."

**Philadelphia's Promise of Filtered Water.**—The board of experts appointed by the mayor of Philadelphia for the study of the water supply and the best means of its improvement has recommended slow sand filtration for all but a small portion of the supply, and for this rapid sand filtration is recommended. The total cost, it is thought, will reach $12,000,000, which it is proposed to raise by a loan. The experts say that plans for the new system can be completed in six months, and that the plant can be completed and in operation within two years.

**The Tenth Congress of Italian Alienists** will be held in Naples, October 10th to 14th, under the presidency of Professor Tamburini, of Modena. The following are the subjects proposed for discussion: (1) Practical methods of individual psychological investigation in asylums and clinics; (2) the light thrown by anatomical data on normal and pathological psychology; (3) psychiatry and the study of the individual and his activity in social relations; and (4) intoxications and infections in the pathogenesis of mental and nervous diseases.

**The Prophylaxis of Malaria.**—The Rome correspondent of *The British Medical Journal* reports an interesting experiment relating to the agency of mosquitos in the spread of malaria. Professor Grassi, of the University of Rome, he writes, recently obtained from the Italian Railway Company leave to use two rooms in a cottage situated near Maccarese, a place well known as malarious, on the line between Rome and Civita Vecchia. The windows of the two rooms were covered with perforated zinc, and for eight days Professor Grassi left home every evening at 5:30, accompanied by a family living outside the Porta San Giovanni, consisting of father, mother, and five children, varying from one to nine years of age, for the above rooms, where they passed the night. The windows of the rooms were left open, but the entrance of mosquitos was prevented by the perforated zinc. Professor Grassi took care that none of the members of the family left the rooms between sunset and sunrise. At about 8 A.M. every morning he and the family returned to Rome. The experiment was completely successful, inasmuch as twelve days after Grassi and the family had returned permanently to Rome not one of them had been attacked with malaria, while during the same time several persons sleeping only 100 metres away from the cottage, and not protected in the same manner, were taken ill with the disease. Professor Grassi and his subjects having slept with open windows naturally breathed the night air of this intensely malarious spot, and they drank the water found there. It may therefore, he says, be deduced that their immunity was due solely to the fact that having protected the windows with perforated zinc those species of mosquitos which produce malaria could not penetrate through the zinc into the rooms.

**The Study of Tropical Diseases.**—The commission from the Johns Hopkins University, with Prof. Simon Flexner at its head, which went to Manila last spring in order to study tropical diseases and to collect material for the use of the new department on that subject, has returned after a successful summer in the Philippines.

**Retirement of Dr. Tryon from the Navy.**—Medical Director and ex-Surgeon-General James Rufus Tryon, of the United States Navy, having reached the age of sixty-two years, has been placed, according to the law, on the retired list with the rank of rear admiral. Dr. Tryon is a New Yorker by birth, and has been in the navy thirty-six years, having been appointed assistant surgeon September 22, 1863. He was assigned to the West Gulf blockading squadron, and later was attached to the Naval Hospital at Boston. He was appointed surgeon in 1873, and surgeon-general in 1893. Upon retiring from this position at the expiration of his four years' term, he went to Spain as United States representative to the International Medical Congress, where he had the distinction of being the last official American to have an audience with the Queen, war at that moment being a foregone conclusion. During the recent war Dr. Tryon was on duty as general inspector of naval hospitals. When in Boston in the early part of his service he showed a special capability in hospital management, and this was, as it were, his specialty while in the service. He designed the United States naval hospital at Yokohama, and it was he chiefly who brought the medical corps and the naval hospitals to that high state of excellence which was commended throughout the world during the war with Spain, and which resulted in such an astonishingly insignificant loss of life afloat, from wounds or disease, during and after the period of hostilities.

**A New Cure for Insanity and Old Age.**—The newspapers report the cure of a case of insanity in Chicago by means of "goat lymph." The happy result was obtained in the case of an inmate of the Kankakee Asylum who had been pronounced "hope-

lessly insane." The report further states that the discoverer of this goat juice is able with it to arrest the progress of senile changes. He has gone to see the other great discoverer of wonderful serums, Dr. R. Koch, of Berlin, in order to induce him to give the remedy a trial on some of his insane compatriots.

**St. Rose's Home for Incurable Cancer.**—Mrs. Rose Hawthorne Lathrop has made a report of the work of this home, established by her in Cherry Street six months ago. The average number of patients in the home has been seven, six having died, and others entering at once. One became so much more comfortable as to be able to return to work.

**Dysentery.**—It is reported from Japan that Kitasato has discovered a bacillus which he claims to be the specific cause of dysentery, or at least of one form of the disease. It is said also that he has had excellent results from the therapeutic employment of a serum obtained by inoculation of this bacillus in animals.

**Burning of a Hospital.**—The Hospital of St. Vincent de Paul in Norfolk was destroyed by fire on September 21st. Three patients were killed and two firemen were injured. St. Vincent's Hospital was four stories high, exclusive of the basement, constructed of pressed brick with stone trimmings, and was one of the best equipped and most complete institutions of its kind in the South.

**The University of Vermont Medical School.**—There has been trouble in the medical department of the University of Vermont, Burlington, for over a year, and this has finally culminated in the resignation of the entire faculty. For some reason the dean of the faculty, who had held that office for several years, was not re-elected a year ago, and this action of his colleagues was resented by him. The students, it is said, sided with the deposed dean rather than with the rest of the faculty. A short while ago a request was made to him to resign his professorial chair and retire altogether from the faculty. Upon his refusal the faculty appealed to the university authorities, and the latter decided that the resignation of the entire faculty would be the best way out of the matter. The faculty thereupon resigned, leaving the trustees free to reorganize the department as they choose. The members of the faculty who resigned are: Drs. A. F. A. King, Washington, D. C.; A. P. Grinnell, Burlington; R. A. Witthaus, New York; J. H. Jackson, Barre; A. M. Phelps, New York; H. C. Tinkham, Burlington; and J. Q. Jenne, St. Albans.

**A Tuberculosis Sanatorium for New York City.**—At a meeting of the State board of health, held on September 22d, it was stated that the conditions in New York City with respect to the existence and treatment of tuberculosis, as shown by the various reports issued by the local board of health, are such as to show the urgent need of active steps being taken for the proper isolation and treatment of patients suffering from consumption who are dependent upon the municipal authorities for medical treatment. In view of this, the board adopted resolutions recommending that the municipal authorities take steps to establish a hospital for consumptives outside of the city limits, and asking the support and co-operation of physicians in an effort to secure action to that end. The authority to establish such a hospital is given, in an act passed by the last legislature, to any city of the first class whenever its board of health shall deem it necessary for the promotion of the health of its inhabitants. It is provided that the city board of health shall select the site, and submit it to the State board for approval. The same act provides that wards for the treatment of pulmonary tuberculosis shall be established in existing hospitals, with separate nurses, cooking-utensils, and washing-facilities and plumbing. Nothing has been done in the matter in this city, and the present action of the State board is probably by way of a hint to the city board.

**Smallpox Quarantine against Mexico.**—Smallpox is reported to prevail very extensively in various places in northern Mexico, and extraordinary precautions are being taken to prevent the spread of the disease over the border into the United States. Every railway station in Mexico on roads leading north is placarded to the effect that no one will be allowed to cross the frontier unless bearing a certificate of health from an officer of the Marine Hospital service in Mexico, or some consul, deputy consul, or consular agent in that country. Detention camps have been established at various points on the frontier.

**To Check Suicide in Chicago.**—It is stated that suicide has become so frequent among the Bohemians (real ones, not table-d'hôte frequenters) of Chicago that special measures are to be undertaken by the Bohemian Brotherhood of America to break up the fashion. This brotherhood, which is a secret organization, and represents a variety of religious beliefs, makes the statement that the prevalence of agnosticism among Bohemians has resulted in suicide in such numbers as almost to threaten the extermination of their race.

**The Manila Medical School.**—A newspaper of Manila states that General Otis has taken the San José College of Medicine in that city out of the hands of the Dominican friars and placed it under the control of the department of education. The Dominicans requested the students to sign a petition in favor of retaining them as professors, but the students refused to do so. Under Spanish rule the College of Medicine was managed in connection with the Santo Tomas University. It was neither established nor managed by the Dominicans, though the Spanish allowed the friars to teach in some of the branches. When the Americans came in, the Dominicans claimed that the medical school belonged to them, but this claim was disallowed by General Otis.

**Licensing Barbers in Michigan.**—The new law providing for the licensing of barbers in all towns in Michigan of over ten thousand inhabitants went into effect on September 22d. The law permits all barbers now in the business to obtain a license upon

making application for the same and paying a fee of $1. Hereafter, however, all persons who desire to engage in the business must pass a satisfactory examination before the State commission as to their proficiency in the use of the razor and shears, as well as of disinfectants so as to prevent the spread of parasitic diseases.

**The Plague** has reappeared in Alexandria, Egypt, two cases, one terminating fatally, having been reported during the past week. The report of cases in the capital of Paraguay has alarmed the South American governments, and the Colombian government has issued a decree closing all the ports of that country to ships with the bubonic plague on board or coming from infected ports. The disease continues at Oporto, but no alarm is now felt in the city, the inhabitants pursuing their usual avocations and complaining only of the injustice of a rigid quarantine. Four new cases were reported on Sunday, making a total of seventy-four cases with thirty deaths since the outbreak of the disease. Dr. Fairfax Irwin, surgeon of the United States Marine-Hospital service, recently visited Oporto in order to collect materials for a report to Surgeon-General Wyman. The members of the French medical mission which was sent to Portugal to investigate the bubonic plague announce that so far nobody inoculated with Yersin's anti-plague serum has died.

**A Gift to the Jefferson Medical College.**—Dr. J. Ackerman Coles, of Newark, N. J., has presented to the Jefferson Medical College of Philadelphia a bust of Harvey, together with the Sydenham Society edition of the works of Thomas Harvey, published in 1847, formerly the property of the late Dr. Abraham Coles, a graduate of Jefferson College in 1835. The bust of Harvey is of heroic size, of Carrara marble, made by Horatio Stern in Rome in 1869. Dr. J. A. Coles has also given a bronze medallion life-size portrait of Dr. Abraham Coles, made by Mr. C. Conrads, of Hartford, Conn., and a life-size bronze copy of the Roman antique statue of the boy extracting a thorn from the sole of his foot.

**A Crematory in New York City.**—A company of undertakers with the strictly modern name of the Automobile Burial Company has been forbidden by the board of health to carry out its plans of starting a crematory on Eighth Avenue in this city.

**Navy Department,** Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending September 23, 1899. September 15th.—Passed Assistant Surgeon George H. Barber detached from the *Monongahela*, on arrival at Newport, and ordered to duty at Naval Academy, September 30th. September 16th.—Passed Assistant Surgeon George Rothganger ordered to duty at the United States Naval Hospital, New York. Assistant Surgeon M. V. Stone detached from the *Brutus* and ordered to the Asiatic station. September 18th.—Surgeon L. B. Baldwin placed on the retired list. September 19th.—Assistant Surgeon R. S. Blakeman ordered to the naval hospital, Newport, R. I., on completion of preliminary examination for promotion. Assistant Surgeon J. J. Snyder detached from the naval hospital, Newport, R. I., and ordered home to be ready for further orders. September 20th.—Surgeon P. A. Lovering detached from the recruiting rendezvous, Buffalo, N. Y., and ordered to proceed home as directed in orders of 12th. Surgeon E. H. Marstcller detached from the recruiting rendezvous, Buffalo, N. Y., and ordered to duty on the *Richmond*. Surgeon G. P. Lumsden detached from the *Richmond* and ordered to the recruiting rendezvous, Buffalo, N. Y.

**Obituary Notes.**—Dr. Thomas George Cusack died at his home in Orange, N. J., on September 20th. He had been in poor health for sixteen months, and his death was due to a complication of diseases. He was born in Orange in 1855, and was graduated from the medical department of the University of New York in 1880. He was a member of the New Jersey Medical Society. He leaves a widow and five children.—Dr. Edward L. Reeves, one of the oldest physicians of Gloucester County, died suddenly at Paulsboro, N. J., on September 20th, in consequence of a second attack of cerebral hemorrhage, at the age of sixty-three years. He was a graduate of the Pennsylvania Medical College of Philadelphia in the class of 1859.—Dr. William Hembel Taggart, of Philadelphia, whose death at Wernersville, Pa., on September 20th, at the age of seventy years, was announced in these columns last week, was graduated from the medical department of the University of Pennsylvania in 1852, and subsequently became a resident physician in the Philadelphia Hospital. In 1857 he was elected to the chair of materia medica and therapeutics in the Philadelphia College of Medicine and in 1859 to the same chair in the Pennsylvania Medical College. At the outbreak of the Civil War he was appointed a surgeon, serving until compelled by ill health to resign. Later he was appointed an acting assistant surgeon in the navy. Dr. William G. A. Bonwill, a well-known dental surgeon, died of uræmia at Philadelphia, on September 24th, at the age of sixty-six years. He was a graduate of Jefferson Medical College, and was well known for his inventions in dental surgery, particularly an electric mallet and a dental engine and rotary saw. He was at one time lecturer on dental surgery in the University of Pennsylvania.—Dr. Francis B. Smith, who was for many years a well-known dentist of this city, died on Saturday, at Stowe, Vt., from apoplexy. On account of failing health he had not been active in his profession for several years, and had lived at Stowe, in which town he was born in 1823. Dr. Smith was graduated from the medical department of the New York University, in 1850, and for some time practised medicine in Stowe. He later came to this city and studied dentistry and engaged in the practice of that profession in this city.—Dr. George A. Hendricks, professor of anatomy in the University of Minnesota, died in Minneapolis on September 24th, of Bright's disease. Dr. Hendricks was a graduate in medicine of the University of Michigan in 1877, and was called from that university to the chair of anatomy in the University of Minnesota in 1889.

# Reviews and Notices.

TRANSACTIONS OF THE TWENTIETH ANNUAL MEETING OF THE AMERICAN LARYNGOLOGICAL ASSOCIATION, held May, 1899. Edited by the Secretary. New York: D. Appleton & Co. 1899.

THE special feature of the present volume of this valuable series is that it contains an elaborate index of the contents of the entire series of volumes issued since the formation of the Association, thus rendering it a most valuable reference book. The present issue contains twenty-nine papers covering a wide range of topics. In addition there are various matters of interest to the members of the Association.

INTERNATIONAL CLINICS: A Quarterly of Clinical Lectures on Medicine, Neurology, Surgery, Gynæcology, Obstetrics, Ophthalmology, Laryngology, Pharyngology, Rhinology, Otology, and Dermatology, and Specially Prepared Articles on Treatment and Drugs, etc. Edited by JUDSON DALAND, M.D. Volume II. Ninth Series. Philadelphia: J. B. Lippincott Co. 1899.

AMONG the many entertaining lectures and dissertations in this volume we note that of Professor Hollander, of Berlin, on superheated air as a hæmostatic and cure for lupus and other affections. Another excellent lecture is that by Professor Grawitz on progressive pernicious anæmia in the adult. A feature of the "Clinics" which makes them valuable is the diversity of material. There are in this issue separate departments for drugs, treatment, medicine, surgery, neurology, gynæcology, ophthalmology, laryngology, and dermatology. The last is filled by one contributor, Lassar, who makes brief remarks upon a variety of topics, including prurigo, pityriasis rosea, localization of syphilis, etc. In all there are over three hundred pages and some illustrations.

TRAITEMENT CHIRURGICAL DU CANCER DU GROS INTESTIN. Par DR. HENRI LARDENNOIS, Chirurgien des Hôpitaux de Reims, etc. Paris: G. Steinheil. 1899.

THIS brochure is an interesting contribution to the subject of intestinal cancer. The author has reviewed the literature of his subject and has epitomized it in this work, with some experiences of his own added. The facts of most importance which are emphasized are that carcinoma of the colon is of slow growth, does not invade the lymphatics early, and can be cured by radical removal at an early stage. Attention is also called to certain errors in diagnosis, which are possible, and there is an interesting discussion of the causes of the cachexia which develops. Operation by one of several methods, with an early diagnosis, affords us the only chance for radical cure, the prospect of which is steadily increasing as we gain in experience. There is, however, nothing novel in these views; they are held by all experienced surgeons.

THE MECHANICS OF SURGERY, comprising Detailed Descriptions, Illustrations, and Lists of Instruments, etc. By CHARLES TRUAX. Chicago. 1899.

THIS is a large volume containing a descriptive compilation of the various forms of surgical instruments and appliances now in use. It is illustrated by nearly three thousand figures, and will doubtless serve a very useful purpose as a work of reference for the surgeon in hospital or private practice.

THE DISEASES OF THE NERVOUS SYSTEM. By PROF. LUDWIG HIRT. Translated by DRS. HOCH and F. R. SMITH. New York: D. Appleton & Co. 1899.

THIS volume is a translation of the second German edition published more than five years ago. It cannot, therefore, be considered strictly up to date. The want of suitable revision is most noticeable in the pages devoted to pathological anatomy and to therapy. The contents of the book are divided into three sections. Section I. includes diseases of the meninges, cranial nerves, and brain proper. Section II. is taken up with a consideration of diseases of the spinal meninges, the spinal nerves, and the substance of the spinal cord. In section III. the general nervous diseases, functional and organic, are described. The chapters on meningitis are unsatisfactory. The classification is not in accord with the modern conception of inflammation of the meninges, and the varieties of the disease are not clearly differentiated. The consideration of diseases of the substance of the brain is prefaced by an adequate presentation of the subject of localization, placed before the reader directly and understandingly. One of the most conspicuous additions to our knowledge of brain diseases during the past few years has been the recognition and interpretation of acute non-hemorrhagic encephalitis. Had the author had an opportunity of recasting the chapter on this subject he would undoubtedly have made many changes and emendations. The chapter on brain tumors is quite satisfactory until we come to the treatment. This is a subject that cannot be adequately disposed of in twenty lines. Hirt remarks that treatment is, in the vast majority of cases, of no avail. There is considerable discrepancy between this statement and the recent statistics of Ferrier, which set forth that surgical interference has given good results in about twenty-five per cent. of properly selected cases. Indeed the reviewer is constrained to say that the volume before us is not a very safe nor a very suggestive treatise for the general practitioner. The neurologist and the teacher will find enough that is new in the way of presentation of facts and recitation of personal experience to compensate him for the time devoted to its perusal and study, but there are a number of treatises in the English language of no greater size that can be more conscientiously recommended to students and practitioners.

LES TROUBLES MENTAUX DE L'ENFANCE. Précis de Psychiâtrie infantile, avec les applications pédagogiques et médico-légales. Par LE DR. MARCEL MANHEIMER, ancien interne des Asiles de la Seine et de la Clinique des Maladies mentales à la Faculté de Médecine des Bureaux de Bienfaisance de Paris. Préface de M. LE PROFESSEUR JOFFROY. Paris: Société d'Éditions Scientifiques. 1899.

THIS is an interesting though concise exposition of an important yet not much-discussed subject. The work is divided into five parts, etiology, symptomatology, nosography, medical jurisprudence, treatment and care. Statistical data are deficient as to the mental disturbances of childhood, but such evidence as is available points to their relative rarity. In young infants during the nursing period, eclampsia is probably the most common manifestation of nervous disturbance. Later, between the third and seventh year, failure in mental development becomes more conspicuous. As growth and development advance, true mental aberration increases in frequency. At puberty impulsive states, hysteria and the like, occur especially. At this period also girls probably suffer more commonly than boys, while earlier the predominance appears to be with the latter. Idiocy and imbecility are more frequent among poor than among rich children. The causes of mental disturbances in children are predisposing and exciting. The former consist essentially in hereditary influences; the latter may be physical or psychic, and others may be complex, as, for instance, educational, social, and the like. The symptomatology includes disturbances of the affections and of the emotions, such as excess in manifestation of pleasure or of sadness, apathy, over-sensitiveness, anger, fear, anxiety; impairment of intelligence, with alterations in attentiveness, in memory, in imagination, in judgment and reasoning, and delirium and hallucinations; modifications of psycho-motor activity—diminution, excess, perversion; and derangement of consciousness—obscuration, stupor, somnambulism, ecstasy. The mental affections of childhood are classified as pure psychoses, mental degenerations, neuroses, states of regression, and toxic delirium. The psychoses include mania, melancholia, and intermittent insanity; the degenerations such simple abnormities as phobias, manias, and sexual aberrations, as well as peculiarities of character, moral insanity, mental instability, hypochondriasis, and states of delirium; the neuroses neurasthenia, hysteria, chorea, and epilepsy; the regressive states the dementia of puberty and general paralysis; and toxic delirium infections, auto-intoxications, and alcoholism. Among medico-legal questions discussed are the responsibility of children, children-criminals, children-witnesses, and suicide among children. The treatment is prophylactic, medical, and psychological. The final section deals with the care of mentally abnormal children, and an appendix contains brief statistical data.

# Society Reports.

## AMERICAN ORTHOPEDIC ASSOCIATION.

*Thirteenth Annual Meeting, Held in New York, May 31 and June 1 and 2, 1899.*

W. R. Townsend, M.D., of New York, President.

(Special Report to the Medical Record.)

*First Day—Wednesday, May 31st.*

**President's Address.**—Dr. W. R. Townsend, in this address, sketched the early history of the orthopedic institutions in New York City, and the development of that special field of surgery.

**Forcible Correction of Lateral Curvature.**—Drs. E. H. Bradford and E. G. Brackett, of Boston, presented a paper on this subject. They stated that when the treatment was carried out with the aid of the Brackett frame or a similar device for making the pressure, it resulted in a diminution of deformity and increased flexibility of the vertebral column. It was specially applicable to cases in the growing stage without much bony change.

**The Class Method of Gymnastic Treatment in Lateral Curvature.**—Dr. Walter Truslow demonstrated this method at the Hospital for the Ruptured and Crippled, and in conjunction therewith read a paper on this subject, giving the results of his observations in this field in the past year and a half. There were, in all, one hundred and ninety-nine cases, of which a little less than half presented postural deformities. Nearly all the pupils who had faithfully followed the treatment had exhibited very decided improvement. The treatment, which was an adaptation of the Swedish movements, aimed so to train the muscles as to allow of their assuming approximately normal positions.

**Some Post-Paralytic Deformities and Their Treatment.**—Dr. Jacob Teschner, of New York, in this communication, stated that in a short time he had succeeded, by invoking the co-operation of other muscles, in securing in many instances very gratifying improvement. The fact that the helpless muscles would often give, with the galvanic current, the reaction of degeneration he interpreted as evidence only that the greater part of the muscle had undergone change—not that it was totally destroyed. The stimulation of these degenerated muscles had been accomplished by stimulation of the associated muscles that were less impaired. His results had demonstrated that when the nerve communications had not been completely destroyed, the function of the remaining muscular fibres could be restored.

Dr. Joel E. Goldthwait, of Boston, opened the discussion on these papers. He had found that the maximum improvement was obtained by the forcible method in a comparatively short time. After this stage had been reached, the chest expansion tended to diminish, and hence he was in favor of applying some form of apparatus which could be removed for exercises, and reapplied. The amount and kind of exercise to be used should be largely determined by the pulse rate. If properly adapted the pulse rate should be slower after than before the exercises.

Dr. John Ridlon, of Chicago, exhibited a modification of the Goldthwait frame which had served him a useful purpose in dispensary work.

Dr. H. Augustus Wilson, of Philadelphia, thought the apparatus usually employed in this forcible method was needlessly terrifying to the patients, and that equally good results could be readily obtained by discarding such machines and using the surgeon's knee as a fulcrum. In this way it was possible to apply the desired force more intelligently than by mechanical means alone. The patient should be seated on a chair with the back to the operator, the pelvis fixed and the hands elevated. The operator should then bend the patient laterally over his knee, and should also rotate the shoulders.

Dr. B. E. McKenzie, of Toronto, thought that the best results were obtained by a combination of individual and class instruction.

Dr. T. E. Satterthwaite, of New York, also spoke in favor of class work, because of the rivalry which it engendered, and preferred manual to machine force.

Dr. Reginald H. Sayre, of New York, said that in certain unusually obstinate cases he had succeeded in effecting an improvement by giving an anæsthetic and breaking up the adhesions by violent manipulation.

Dr. W. E. Wirt, of Cleveland, said that he was accustomed to reduce the deformity by suspension and posture; then to make a plaster-of-Paris mould, and on this model an over-corrected corset. If the gymnastic classes consisted of more than five pupils, the details of the treatment were apt to be neglected.

Dr. R. Tunstall Taylor, of Baltimore, remarked that the gymnastic exercises could be made more effective by having them carried out before a mirror.

**Congenital Deformities of the Spine.**—Dr. Augustus Thorndike, of Boston, presented a communication on this subject, which was profusely illustrated. In regard to spina bifida he stated that the present opinion was in favor of excision whenever rupture had occurred or was imminent. It was rarely successful as a means of relieving paralysis.

**The Diagnostic Value of Radiography in Orthopedic and General Surgery.**—Dr. Louis A. Weigel, of Rochester, discussed this subject by the aid of many lantern views. In a rather large experience with the *x*-rays he had not had one mishap, and this he attributed chiefly to the observance of the rule always to have the vacuum tube at least eight inches away from the subject. When *x*-ray burns occurred, the fault was with the operator and not with the particular form of apparatus employed. He had used both the coil and the static machine in this work.

**Biographical Notes on Subcutaneous Tenotomy.**—Dr. A. B. Judson, of New York, in a paper with this title, gave a brief historical account of some of the pioneers in this field.

**Report of the Committee on Recording Lateral Curvature.**—The conclusion reached by this committee, after careful inquiry and much deliberation, was that photography was at present the best-known method for recording lateral curvatures.

Dr. McKenzie opened the discussion by the statement that he had at last discarded all the other methods in favor of what he significantly termed "honest photography."

Drs. Shaffer, Lovett, and H. A. Wilson took the same ground, the last-named gentleman emphasizing his remarks by the statement that the reason that photography excelled all other methods was that it reduced the personal equation to a minimum, and its record allowed of ready interpretation.

Dr. Henry Ling Taylor, of New York, took issue with him on this, asserting that every practical photographer would bear him out in the statement that, without the slightest intention of deception, numerous inaccuracies and errors were prone to creep in.

After Drs. Truslow, Dane, and C. E. Young had described simple, every-day methods of recording lateral curvature cases, the association voted that it was inexpedient at present to indorse any one method.

**Pigeon-Toe.**—Dr. W. Burton Hopkins, of Philadelphia, described and demonstrated an ingenious mechanical device for use in cases of pigeon-toe. By

means of a curious combination of a swivel and spring embedded in the heel of the shoe, the foot was thrown out as the person wearing it walked along.

Dr. L. W. Hubbard, of New York, remarked that this device would be inapplicable to most of the cases of pigeon-toe that he had seen, as they had been in young children without high-heeled shoes.

Dr. Royal Whitman, of New York, was of the opinion that this condition was always indicative of weak feet.

Dr. C. C. Foster, of Cambridge, thought a cure could be most easily effected by a suitable military drill.

Dr. H. A. Wilson remarked that it had been demonstrated that this device actually produced rotation at the ankle-joint.

---

*Second Day—Thursday, June 1st.*

**A Study of Pott's Paraplegia as Affected by Correction of the Spinal Deformity.**—Dr. Joel E. Goldthwait, of Boston, described in this paper his experience in eleven cases. Some of the cases narrated were of peculiar interest because of the rapid disappearance of the paralysis after the application of the jacket, and its equally speedy return when the support was removed or became inefficient.

Dr. V. P. Gibney, of New York, referred to a case of Pott's paraplegia that he had had under observation, in which relief had followed the operation of laminectomy and the removal of a granulomatous mass.

Dr. R. Lovett, of Boston, thought the very rapid improvement observed in some of Dr. Goldthwait's cases might be explained on the well-known hypothesis that the pressure symptoms were due to lymphatic œdema.

Dr. Goldthwait remarked that while his cases had been relieved, in not one had there been a permanent recession of the deformity.

**Osteoarthritis of the Spine in Spondylitis Deformans.**—Dr. J. E. Goldthwait also presented this paper. In it he treated systematically of the etiology, pathology, and treatment of this remarkable disease, which, he said, belonged to adult life. Complete recovery from the paralysis was unknown. The treatment should be stimulating.

Dr. Ridlon related the history of a case occurring in a woman of twenty-five years, in which, much to his surprise, he had given her great relief by violent manipulation under general anæsthesia.

**Operative Treatment of Congenital Luxation of the Hip.**—Dr. G. G. Davis, of Philadelphia, under this head described and exhibited the instruments used by him in making the new acetabulum. The essential feature of the method consisted in using a wood-carver's gouge and a "rose burr."

**A Case of Dorsal Dislocation of the Hip Occurring Spontaneously during the Course of an Acute Osteomyelitis of the Neck and Shaft of the Femur.**—Dr. W. J. Taylor, of Philadelphia, reported this case. An extensive osteomyelitis had followed an apparently insignificant injury received in a game of foot-ball, and this, in turn, had led to a spontaneous dislocation.

**Reduction of Congenital Dislocation of the Hip by the Lorenz Method.**—Dr. W. E. Wirt, of Cleveland, reported two cases so treated.

**Congenital Dislocation of the Hip.**—Dr. Harry M. Sherman, of San Francisco, read this paper. He stated that he had done the bloody operation on nine hips, and had operated on thirteen hips by the bloodless method. In three of the first group there had been a relapse after it had been supposed that good ankylosis had been secured; in the others the reduction had been permanent, but there had been ankylosis except in two or three cases. In seven of the cases treated by the bloodless method relapse had occurred. On account of these disappointing results, he purposed in the future to make digital exploration, and endeavor by punching out an acetabulum in an upward and inward direction to secure, with less risk, the desired depth.

**The Kyphotone.**—Dr. R. Tunstall Taylor exhibited this machine, which is intended to correct forcibly the deformity of Pott's disease. He claimed that the apparatus was simple and inexpensive, and by its aid jackets could be quickly and effectively applied.

**Celluloid Jackets.**—Dr. Augustus Thorndike opened a discussion on this topic by the statement that the process recommended by him last year had proved disappointing, as had most of the other methods that he had tried.

Dr. R. H. Sayre said that beautiful corsets could be made by applying to a suitable mould sheets of celluloid which had been softened by exposure for eight hours to the fumes of acetone. The trouble was that these corsets were so hot that even though they were freely perforated the patients would often refuse to wear them.

Dr. E. G. Brackett remarked that another drawback to their use was that if removed from the mould before the expiration of two or three weeks, they would be ruined by the curling up of the celluloid.

**Treatment of Congenital Dislocation of the Hip.**—Dr. Royal Whitman discussed this subject in connection with the exhibition of a considerable number of patients that he had treated. He had operated on twenty-one patients by the bloodless method, all more than two years ago. Fifteen of his cases of open operation had been treated during the present year. He had treated twenty-seven cases by the functional method of Lorenz, and seven by both methods. There had been three perfect cures by the bloodless method, and he had even succeeded in securing an excellent result by this method in a girl of seven years.

**Congenital Dislocation of the Hip.**—Dr. T. Halsted Myers, of New York, exhibited a child of three years upon whom he had successfully operated by the bloodless method four years ago. He had operated altogether on sixteen cases, five of which would probably yield a perfect result.

Dr. B. E. McKenzie said that he expected to get a good result in a child of nine years upon whom he had operated.

Drs. Ridlon and H. A. Wilson disputed Dr. Whitman's assertion regarding the great disability produced in adults by congenital dislocation of the hip, and Dr. Wilson added that, in view of the high rate of mortality and the liability of ankylosis following the open operation, it seemed well to enter a plea for greater conservatism in this class of cases.

Dr. Sherman complimented Dr. Whitman on the excellent showing that his cases had made, and added that they were greatly superior to any that had been shown him by Lorenz himself four years ago.

**Symmetrical Enlargement of Both Legs from Possible Lymphangitis.**—Dr. S. Ketch, of New York, exhibited this case, and Dr. W. R. Townsend showed a photograph of a similar case, except that the enlargement had been unilateral.

**Enlargement of Tibial Tubercles.**—Dr. Henry Ling Taylor, of New York, presented two cases in which this was present. One was in a boy of twelve and the other in a boy of sixteen years. In one of the cases only was there a history of trauma.

Several similar cases were reported in this connection, and the general opinion seemed to be that this enlargement was most likely to occur in athletes.

**Partial Luxation of the Humerus following Anterior Poliomyelitis.**—Dr. J. H. Waterman, of New York, exhibited a youth in whom irritation of the pectoralis major caused dislocation of the humerus.

**Spasmodic Torticollis.**—Dr. Charles E. Thomson, of Scranton, presented two cases of this kind. One had already been relieved by several sections of nerves.

**Tuberculosis and Purulent Joint Abscesses Treated with Carbolic Acid.**—Dr. A. M. Phelps, of New York, described the results that he had thus far obtained by an adaptation of Dr. Seneca D. Powell's method of treating abscess cavities by successively irrigating them with pure carbolic acid, alcohol, and water. He expressed himself as very much pleased with this new treatment, and called attention to the remarkable saving in time effected.

**Multiple Deformities of Extremities.**—Dr. George R. Elliott, of New York, reported a case of this kind, apparently the result of changes in the nervous system produced by traumatism during intrauterine life.

Drs. Edward D. Fisher and S. B. Onuf commented on the neurological aspects of this rare case.

**Pointers on the Leather Splint.**—Dr. A. J. Steele, of St. Louis, gave some useful hints as to the practical working of leather intended for use in corsets. He attached great importance to his method of binding the leather on to the model, and to the baking of the leather at a temperature of 180° to 190° F. for two or three days.

---

*Third Day—Friday, June 2d.*

**An Unusual Case of Fracture of the Femur.**—Dr. C. L. Starr, of Toronto, reported the case of a child in whom he had at first quite confidently made a diagnosis of separation of the upper epiphysis of the femur. This child happening to die subsequently from diphtheria, an opportunity had been afforded him for a post-mortem examination. To his surprise he had learned that there had not been a separation of the epiphysis, but a fracture just beyond the junction of the head and neck. The case was interesting because this child of three years had a history of limping for only two weeks. When first seen by him there had been the typical limp of a congenital dislocation of the hip; there had been no complaint of pain, and there was no history of injury. After the autopsy he had ascertained that the child had fallen from a high chair six weeks prior to the time when the limp had been first noticed. It was probable that there had been first an impaction, and subsequently a dislodgment of the fragment.

**Position Symptoms in Joint Disease.**—Dr. Harry M. Sherman, of San Francisco, presented in this paper an exhaustive study of the phenomena observed in joint disease and of the various theories that had been propounded to explain them. He rejected the theories of Hilton and of Phelps, so far as they were based on one group of muscles, and laid great stress on the existence of a spot of bony weakness, the result of the tuberculous process, of which the organism was evidently cognizant.

**Some Salient Points in the Treatment of Hip Disease.**—Dr. B. E. McKenzie, of Toronto, read this paper. He recommended the brace of Mr. Thomas, or some of its modifications, taking care to secure sufficient bending at the knee. He no longer believed that the splint should also act as a crutch. By making traction on the side opposite to the one affected, muscular spasm was controlled and the tendency to adduction counteracted.

**The Conservative Surgical Treatment of Tuberculous Diseases of the Joints.**—Dr. C. L. Starr, in this paper, advised treating tuberculous cavities by incision, curetting, swabbing with carbolic acid or chloride of zinc, the injection of iodoform emulsion, and finally by packing with iodoform gauze.

**Additional Views of the Treatment of Hip Disease.**—Dr. A. B. Judson read a paper with this title (see page 569).

**Rheumatoid Arthritis.**—Drs. R. T. Taylor and S. H. McKim, of Baltimore, presented a joint paper on this subject, in which they described some of the clinical features of this malady. They stated that the disease was usually bilateral, and that a characteristic feature was the involvement of the cervical portion of the spinal cord. The glands chiefly enlarged were those in the vicinity of the affected joints. They showed no tendency to break down. The skin often assumed a peculiar waxy appearance. Treatment was of but little avail, neither curing nor controlling the disease.

**The Operative Treatment of Old Subcoracoid Dislocations.**—Dr. Griffith, of Kansas City, reported three cases of this kind in which he had been unable to reduce the dislocation after making a very long incision and resorting to violent manipulation. Finding the long head of the biceps an obstacle to reduction, he had severed it, and then with a blunt-pointed periosteotome had been able to throw the head of the bone into position. Having observed this effect of division of the long head of the biceps in the first case, he had had made a long, stout, and specially curved periosteal elevator. With this instrument it had been very easy to replace the bone after division of the muscle. He had not the slightest doubt that the deaths reported in connection with these cases had been the result of the violent manipulation and extension that had been practised after having opened into the joints. There had been no subsequent trouble from the divided head of the biceps.

Dr. G. G. Davis remarked that in operating on one of these cases he had been compelled to dissect away nearly three-fourths of the attachment of the pectoralis major, and even divide the attachments of the supra- and infraspinatus muscles as well as the capsule below the head of the humerus.

**Heat as a Therapeutic Measure.**—Dr. S. L. McCurdy, of Pittsburg, read a paper with this title, in which he gave the results of some observations that he had made regarding the effect on the temperature of the deeper structures. The object of this study was to determine whether or not the therapeutic application of heat exerted any influence on bacterial life. It was plainly shown that the temperature of the deeper structures was unaffected.

Dr. Wirt remarked that whatever therapeutic effect heat might have was to be ascribed, not to its influence on bacteria, but on the blood-vessels, lymphatics, and nerves of the part treated.

**Surgical Intervention in Cases of Spastic Paralysis.**—Dr. B. E. McKenzie, of Toronto, presented this paper. He stated that according to his observations in more than sixty per cent. of these cases there had been deficiency in intellect. They could be divided into three groups, viz.: (1) Those due to parental conditions, (2) those occurring after birth, and (3) those dependent upon trauma occurring subsequently. Until the time had arrived when a child could sit erect and show some disposition to balance the trunk on the extremities, nothing could be done in the way of surgical treatment. The spastic state of the abductors, the hamstrings, and the muscles controlling the feet offered an insuperable obstacle to walking. It had been his practice to cut the abductors and then abduct the limbs so as to place them at an angle of from 60° to 90°, and retain them in this position for several weeks. In no case had there been any return of the contrac-

tures. By such treatment patients that had no prospect of ever walking at all could be made to walk quite readily and nicely. Massage should be practised for years after operation.

Dr. S. Ketch said that he had arrived at about the same conclusions as the author of the paper. He preferred to divide these cases into: (1) Those in which there is absolutely no mentality; (2) those in which the mentality is impaired; (3) those in which the mentality is normal. He would base his prognosis and, to a certain extent, the treatment, on the mental state. He had tried the effect of tenotomy in quite a number of idiots, and had been pleased not only in the improved mental condition, but in the permanency of reposition after the operation in these cases of spastic paralysis. He believed that by proper education and environment alone the gait of these children could be improved. Until the time had arrived when the contracture of the tendon had become more or less permanent, and the irritation from the brain or cord had begun to lessen, it was not proper to resort to tenotomy. When this operation had been done in young children exhibiting evidence of spasm, the results had not been so good as in older children. The incubus of mechanical apparatus in these defective children was rather harmful than beneficial.

Dr. Ridlon said he believed all these children should be operated on when young, because the irritation would be relieved and the mental condition would often be benefited. If there was a certain amount of relapse, the operation should be repeated, if necessary more than once. The part most contractured should be cut first, and that was usually the tendo Achillis, and then there should be an interval of two months before doing another tenotomy. If this was done, it would often be found unnecessary to cut the hamstrings at all. Mechanical appliances had been disappointing to him in these cases. A rather curious fact, learned from personal experience, was that if plaster was kept on for from four to six weeks, braces would not be required afterward.

Dr. Sherman said that he cut the tendons freely, and separated the legs as widely as possible; if they relapsed, he repeated the operation.

Dr. Judson relied upon education as the chief element in the treatment, but employed in addition suitable mechanical treatment when the locomotion was interfered with by the existence of a talipes equinovarus.

Dr. Newton M. Shaffer, of New York, said that he had learned to defer treatment until the stage had been reached in which the spasticity diminished; he strongly objected to operating while the spasticity was very pronounced.

Dr. E. H. Bradford said that the cure was much more rapid and satisfactory when tenotomy was done at the proper time than when the case was left to itself and such surgical interference was withheld.

Dr. Weigel referred to two severe cases reported by him several years ago in which the good result had been permanent.

Dr. McKenzie, in closing, said that he had commonly found the adductors more at fault in these cases than the tendo Achillis.

**The State Care of Indigent Crippled Children.**—Dr. Arthur J. Gillette, of St. Paul, described under this title the efforts made in Minnesota to induce the legislature to establish a State institution for the care of these helpless ones. Persistent efforts during two sessions of the legislature had finally been crowned with success, and the hospital was now a reality.

**The Cause of Failure after Phelps' Operation for Club-Foot.**—Dr. Daniel La Ferte, of Detroit, read this paper. He expressed the belief that the division of the tendo Achillis should be the final instead of the initial step in the operation. When the equinus could not be corrected it was because the astragalus could not be pushed in between the malleoli; here he would advise the removal of the astragalus.

Dr. W. O. Plimpton explained that the object of cutting the tendo Achillis first was to afford better leverage when the operator desired to bring down the heel.

**Prothesis, a Branch of Orthopedic Practice.**—Dr. A. B. Judson presented in this brief paper an account of some of the more important mechanical devices which he used in his work, with the idea of giving greater prominence to this part of the work of the orthopedic surgeon.

**Preliminary Report of a Study of Shortening of the Tibia in Connection with Tuberculous Disease of the Hip.**—Dr. Russell A. Hibbs presented this report, based on a study of forty-one cases. He asserted that shortening of the tibia was to be expected in a large proportion of the cases of hip disease lasting more than one year.

## INTERNATIONAL CONGRESS OF GYNÆCOLOGY AND OBSTETRICS.

*Held in Amsterdam, August 8, 9, 10, 11, and 12, 1899.*

(Special Report to the Medical Record.)

### SECTION OF OBSTETRICS.

*Fifth Day—Saturday, August 12th.*

(Continued from page 464.)

**Antisepsis in Cæsarean Section and in Symphyseotomy.**—Dr. Treub, of Amsterdam, emphasized the resisting-power of the peritoneum against infection, due to its great absorbing-power and its tendency to produce adhesive inflammation. On the contrary, loose connective tissue was ill adapted to resist infection. He therefore concluded that, *cæteris paribus*, symphyseotomy was a more dangerous operation than Cæsarean section, because it exacted a greater degree of antisepsis.

**On the Definition of the Presentation and the Position of the Fœtus.**—Dr. La Torre, of Rome, read this paper. This was a refutation of the definition proposed by Runge in his "Treatise on Obstetrics," and a support of the generally accepted definition, originally proposed by Madame Lachapelle.

**Researches in Regard to the Elimination of Methylene Blue in Normal and Pathological Pregnancy.**—Dr. H. van de Velde, of Amsterdam, having made numerous injections of methylene blue during pregnancy and after delivery, had seen that Achard Castaigne's experiment might be of real value in estimating the importance of an albuminuria of pregnancy. In cases of eclampsia this method gave many useful indications for the diagnosis of complications, for therapeutical proceedings, but specially for the prognosis. In several of these cases the author watched the passing of the injected blue into the contents of the uterus; in the amniotic liquid he had never found the blue itself, but only chromogen, a derivative of the blue; the urine of the fœtus, however, was colored blue several times. These facts, together with other observations, made him conclude that the mother played a greater part in the production of amniotic liquid, even in the last days of pregnancy, than the child did. At the end of his communication he related a case of hydrorrhœa uteri, in which the hydrorrhœic liquid (probably the maternal part of the amniotic liquid, now produced in excess and no more passing

through the amnion) contained chromogen, while in the amniotic liquid no trace of this substance or of methylene blue was to be found.

**Anaplastic Amputation of the Cervix in Regard to Subsequent Pregnancy.**—Dr. Chaleix-Vivie, of Bordeaux, read this paper. He presented personal statistics of 17 cases of this operation. These 17 women had, subsequent to operation, 23 pregnancies, of which 19 were labors at term and 4 miscarriages (all from causes other than the operation). Labor was in nearly all instances normal. His conclusion was that the operation had no evil influence on the duration of pregnancy, the progress of dilatation, the rupture of the bag of waters, or the nature of the presentation. Schroeder's operation was to be preferred, because it allowed ablation of the intra-cervical mucosa.

**Insufflation of Air into the Uterine Cavity as a Means of Preventing Asphyxia of the Fœtus during Labor.**—Dr. Rapin, of Lausanne, contributed this paper. The author related three cases in which he had used the means indicated. The idea was his own. Without being able to draw definite conclusions, he remarked that the infants, under very unfavorable conditions, had been all born alive; that in no case had the procedure interfered with the progress of labor nor with the pains; and in especial, that in no case was the fœtal respiratory tract obstructed by mucus and amniotic fluid, a point very favorable to resuscitation when necessary. The theoretical dangers of infection, of over-distention, of air-embolism, and of technical difficulties did not practically exist. He would recommend the procedure: (1) in all cases of procidentia of the cord; (2) in breech presentations, when labor is retarded; (3) in shoulder presentations, at the beginning of version, or after the knees had been brought to the vulva. Counter-indications were: death of the fœtus, septic phenomena during labor, and possibly placenta prævia (?).

**Indications for Cæsarean Section as Compared with Those for Symphyseotomy, Craniotomy, and Premature Induction of Labor.**—Dr. Fancourt Barnes, of London, opened the discussion on this subject. There was no doubt, he said, that the practice of obstetricians of repute in the present day was to widen the limits previously enforced for the performance of the Cæsarean operation. The enormous mortality which attended the operation twenty-six years ago, and which was computed in 1880 from a series of one hundred and thirty-eight cases, by Harris, at 81.2 per cent., had been so far reduced that in experienced hands it was little higher than that of ovariotomy. Thus Leopold, of Dresden, had reported fifty cases with a maternal mortality of eight per cent., and Olshausen last year a series of twenty-nine with a maternal mortality of only 6.8 per cent. This result was due entirely to the improvements introduced during this period in the technique of abdominal surgery, and especially in the method of suturing the uterine wound. The question therefore now arose whether the Cæsarean operation should not be performed in order to save the child, in circumstances previously regarded as necessitating craniotomy. Another recent tendency which was becoming more and more manifest was to regard operations involving the destruction of a living child in utero as unworthy of the present high efficiency of the obstetric art. If we set aside, then, craniotomy on the living child, there were three alternative procedures, viz., induction of premature labor, symphyseotomy, and the Cæsarean section. Induction of premature labor was of course limited in its applicability to cases in which the patient came under observation during pregnancy, and a prognosis of difficult labor could be established. The limits of pelvic space requisite for the passage of a viable child were well recognized and required no comment. The methods of starting labor had received no notable additions in recent years. The maternal mortality of the operation in competent hands was probably not more than one to two per cent., but the fœtal mortality was unfortunately high, being placed by the most successful operators at thirty-three per cent. No amount of technical skill could diminish this high rate of fœtal mortality, for it depended upon conditions over which the operator had no control, viz.: (1) The delicacy of the premature infant, and its consequent liability to suffer from the effects of labor; (2) the frequent necessity for interference during labor owing to malpresentations, and deficient uterine action; (3) the liability of the child to perish from malnutrition within the first few weeks of extra-uterine life. The other two alternatives, symphyseotomy and the Cæsarean section, being operations performed at term, naturally offered more favorable chances for the child. Under conditions which prevented the delivery of a living child *per vias naturales*, these two operations offered the only practical alternatives. Symphyseotomy must of necessity be very strictly limited in its application by the amount of pelvic space available. The object of the operation was to obtain a temporary increase in the size of the pelvis sufficient to allow the delivery of a live child by forceps, as an alternative to craniotomy. The amount of increase in the conjugate which could be safely obtained in this manner without injury to the sacro-iliac synchondrosis was only half an inch; the operation was therefore applicable to only a small number of cases, viz., those which lie just outside the limits within which delivery by forceps or turning can be effected. The mortality of the operation had always been and still remained a large one, for a surgical procedure apparently so simple; even in the hands of Pinard the mortality from 1892 to 1896 was 10.84 per cent. for the mothers, and 14.5 per cent. for the children. It will be observed that these figures compare unfavorably with those of Cæsarean section already mentioned, the mortality of symphyseotomy being actually more than double that of Cæsarean section. Comparison of Cæsarean section with symphyseotomy, in the light of modern results, seemed entirely in favor of the former. There were no limits to the application of the Cæsarean operation; it could be performed in the worst cases of pelvic contraction; in obstruction by uterine or extra-uterine tumors it offered not only a means of delivery, but also could be combined with complete removal of the cause of the obstruction; when the obstructing cause was irremovable, the patient could at the same time be sterilized and thus saved from the recurring risk of future pregnancy; it was undoubtedly the most rapid means we possessed of emptying the uterus, and might therefore find application in conditions of urgency, apart from obstructed labor; and lastly the mortality attending it, both for the mother and the child, was less than that of symphyseotomy, and was steadily diminishing. The following table compared the most recent statistics of the two operations:

| | Maternal Mortality. | Fœtal Mortality. |
|---|---|---|
| Symphyseotomy..... | 10.8 per cent. | 14.5 per cent. |
| Cæsarean section..... | 7.6 " | 7.6 " |

If we now referred to the operations done during the last ten years in the Royal Maternity Charity of London we were met on the threshold of our inquiry by the complete absence of the Cæsarean section. During those years no less than forty thousand women were delivered, and among these deliveries no indication for Cæsarean section had presented itself. The explanation of this remarkable fact was a simple one. It was explained by the absence of pelvic deformity

in the city of London. This absence was undoubtedly due to the improved and still improving hygienic conditions under which the poor of London exist. Craniotomy was required in only fourteen cases out of the forty thousand, which sufficiently proved the rarity of pelvic deformity. The conclusions at which he arrived were: (1) As regards symphyseotomy he considered that the operation had not justified its existence, and he could not help thinking that in a few years the eminent obstetricians who had been advocating it would abandon its use. (2) Induction of premature labor, within certain limits, would always hold a recognized and useful position among obstetric operations. (3) And lastly we were forced to the conclusion, after a careful study of the latest figures which have been published on Cæsarean section, that it was a scientific and justifiable operation, and that it would be more widely resorted to in the future, as the science of obstetrics advanced, than it had been in the past.

Dr. Leopold, of Dresden, made a very exact classification of the various degrees of pelvic deformity and distinguished between the cases of primiparous and those of multiparous women. Three degrees of contraction ought to be distinguished: (1) The conjugata vera was more than 7 cm. in the contracted non-rachitic or rachitic pelvis, more than 7.5 cm. in the justo-minor pelvis; (2) the conjugata vera was less than 7–7.5 cm., but more than 6 cm.; (3) the conjugata vera was less than 6 cm. In the first group primiparæ generally had a tolerably good labor. When the head did not enter the pelvic brim—perhaps on account of a bad presentation (the case approached the second group)—a distinction was to be made between cases treated in hospital and in private practice. In the hospital Professor Leopold did not hesitate to perform the Cæsarean section when all other means had proved useless and when mother and child were in good condition. When the child was in danger he preferred craniotomy, certainly the only legitimate operation when the child was dead. In private practice craniotomy was the only indicated operation when the head was retained by a pelvis too narrow to allow the passage of a living child. Though Pinard had given as his opinion that "craniotomy of the living child ought never to be performed," and that "embryotomy of the living child is condemned," Professor Leopold, appreciating the ideal view taken by the celebrated French obstetrician, agreed with Dr. Charles of Liège, "that it is not easy to act up to these rules." Doubtless craniotomy of the living child ought to be avoided as much as possible, and an operation inoffensive for the child ought to take its place, but in difficult cases in private practice, craniotomy, which saved the mother, was preferable to Cæsarean section or to symphyseotomy, which gave a considerable maternal mortality. In the third group Cæsarean section alone was indicated, forceps and version being impossible, and the extraction of the child after perforation, even after symphyseotomy, being very difficult, if not counterindicated. With multiparæ the difficulties of labor were greater because of the greater weight of the fœtus and the lesser intensity of the contractions of the uterus and the abdominal walls. In private practice the premature induction of labor, either by the bougie or by the intra-uterine bag, was and would be the choice operation in the pelves of the first group, notwithstanding the brilliant results of Cæsarean section and of symphyseotomy. The results of premature labor were very satisfactory. Many obstetricians had noted from sixty to eighty per cent. living children when the patient left the hospital the eleventh day post partum. In the pelves of the second group craniotomy should be performed when the child was dead. Professor Leopold preferred also craniotomy to the other operations when the child was in danger or the mother exhausted or ill. When the child was in good condition, Cæsarean section or symphyseotomy could be done in hospital practice (personally Leopold preferred the former operation). In private practice these two operations might be now and then preferred to craniotomy, when the obstetrician was very skilful, had sufficient assistance, and when the woman was in very good condition. In the third class of pelvis, Cæsarean section was the only operation indicated, alike for primi- or multiparæ, symphyseotomy being forbidden by the excessive contraction of the pelvis.

Dr. Pinard, of Paris, read a paper which, besides being a reiteration of his well-known views, contained elaborate statistics of one hundred symphyseotomies done in the Clinique Baudelocque, and of all the cases of contracted pelvis during the year 1898 at the same clinique. He began by defining, according to his ideas, the intrinsic value of each of the four operations under discussion:

Cæsarean operation: Theoretically, this operation was ideal. Both mother and child were in good condition; and the child underwent no traumatism. Practically, statistics bore this out to a certain extent. A *résumé* of Leopold's, Olshausen's, and Zweifel's statistics gave the following: The conservative operation, 5.8 per cent. mortality; the Porro operation, 3.7 per cent. mortality. Such were the results, but by the best operators and in the best conditions.

Symphyseotomy: This was an easy operation. He presented detailed statistics bearing upon 100 cases during the past seven years at the Clinique Baudelocque. The maternal mortality, he could claim, was five per cent., excluding 7 deaths due to outside causes. The infantile mortality was six per cent., excluding 7 cases in which, (1) forceps had been applied at the brim before the operation; (2) lesions of the cranium were caused by an incomplete symphyseotomy; (3) induced labor; (4) accidental broncho-pneumonia. He would remark in addition that 22 of the women operated upon had had ulterior pregnancies; that of these 6 were operated upon successfully for the second and third time, while 16 had spontaneous labors.

Craniotomy: Here maternal mortality should be *nil*; yet in 81 cases in the Baudelocque Clinic there was a maternal mortality of 11.5 per cent. This was evidently mainly due to sepsis.

Induction of premature labor: He acknowledged the innocuousness for the mother, but ascribed to it an infantile mortality of thirty-three per cent.—a mortality which could never be much reduced.

Continuing, Dr. Pinard laid down the principle that the physician should never destroy life; he had absolutely not the right. Neither had he the right to discuss intervention on the basis of the comparative moral or social value of the life of mother and child. For these reasons he rejected absolutely both embryotomy on the living child because it destroyed life deliberately, and also induced labor because it was attended with so much greater an infantile mortality than the other operations. He would admit to discussion only symphyseotomy and Cæsarean section. The advantages in favor of the latter were the following: It was an easy operation, which could be done at the beginning of labor before either infection of the mother or injury of the child, and extraction was without danger for the child. The danger was the opening of the peritoneum. Symphyseotomy could not be done at the beginning of labor; it was only a preparatory operation which had to be followed by extraction through soft parts which were usually not dilated. He recognized all this, but the immense advantage of not opening the peritoneal cavity made him prefer without hesitation symphyseotomy in all cases in which it was practicable. And he was absolutely con-

vinced that, in non-infected women, it was less dangerous than Cæsarean section.

Dr. Pestalozza, of Florence, concluded that induced labor was justifiable in certain cases. It was altogether innocent for the mother, with aseptic precautions. Certainly the fœtal mortality was great; but he believed that errors were much more frequently made in inducing it too early than too late, and this would partially account for the high mortality. Symphyseotomy he had done seven times with one death from hemorrhage (rupture of the vagina), and without infant mortality. Cæsarean operation was absolutely indicated with a true conjugate below 7 cm.; above this it was relatively indicated. The conservative operation was to be preferred. As between embryotomy and Cæsarean section, in a hospital, the latter was always to be preferred.

**Total Abdominal Hysterectomy for Uterine Cancer.**—Dr. Faure, of Paris, contributed this paper. He would advise vaginal hysterectomy only in very early cases of cervical disease. In all others he would use the abdominal route. He preferred his own operation (by median section and dissection from below upward of each half). To avoid oozing during operation he would recommend placing a temporary ligature on the hypogastrics. He had done five abdominal hysterectomies for cancer, with two deaths, one rapid recurrence; the two others (the last one done eleven months ago) were still without recurrence.

**Operative Treatment of Salpingitis.**—Dr. Hartmann, of Paris, contributed this paper. He recalled his paper of 1896 at Geneva, in which he had upheld the abdominal route as against the vaginal in removing suppurating adnexa. Since then, having carefully followed his old cases, he had found that only fifty-five per cent. of them had been complete cures. The other patients complained of pelvic symptoms, although certainly these were usually not severe. On examination he had found either a persisting metritis or indurated nodules at the site of the pedicles. He had therefore since then removed the uterus in all cases in which it was useless, *i.e.*, when the necessity of removing the adnexa on both sides was definite. At the same time he always endeavored to save an ovary. He had also suppressed the pedicles by doing isolated ligature of the vessels and by re-covering the pelvic floor with peritoneum. By these methods he could claim perfect ultimate results. He had done 72 operations for salpingitis since 1896; 40 total abdominal castrations, of which 26 were for suppurative lesions; 22 conservative abdominal operations (9 suppurative); 10 posterior colpotomies for suppurative salpingitis. In these cases he had had one death, *i.e.*, 1.38 per cent. mortality. In conclusion, he would absolutely reject the vaginal route for inflammations of the adnexa, save that posterior colpotomy was still indicated for large and easily accessible collections; this, moreover, in many cases would have to be followed by a complete abdominal operation.

**Of Periodical Intermenstrual Pains.**—Dr. Brodier, of Paris, laid down as a distinct clinical entity a class of cases presenting the following symptomatology: Pains, usually in the suprapubic region, not severe, commencing usually about the fifteenth day after the beginning of the last menstruation, lasting four to six days; affecting mostly women from twenty-five to thirty-five years of age; altogether afebrile; unaccompanied by any discoverable ovarian or uterine lesion, save occasionally a slight cervical catarrh; not benefited by curetting or electricity; disappearing during pregnancy; accompanied in many by vesical tenesmus. He had watched one case very carefully, and had concluded the pains were due to pressure of the uterus on the bladder.

**Rational Surgical Treatment of Cancer of the Breast.**—Dr. Schmeltz, of Nice, read this paper. He began by declaring himself a partisan of the parasitic theory. He thought infection was caused as in rhinoscleroma and actinomycosis. Considering the frequency of recurrence after cutting operations, he was led to try the following method: He did not close the wound, but applied to the raw surface after operation a caustic paste. He had done this in over two hundred cases in the last ten years, and had had only five or six recurrences.

Dr. Schmeltz also presented a new thermo-insufflator of his own device for the treatment of various gynæcological conditions. He was strongly in favor of thermo-insufflation.

Dr. Jayle, of Paris, remarked that in his hands the results in metritis of the cervix had not been encouraging. He had devised a similar instrument some two years ago.

**Treatment of Vaginal Cystocele by a Special Procedure of Abdominal Cysto-Hysteropexy.**—Dr. Laroyenne, of Lyons, presented a communication on this subject. He performed laparotomy, fixed the postero-superior part of the bladder (constituting the cystocele) to the anterior surface of the uterus, and fixed its anterior surface to the anterior abdominal wall. He finally fastened the uterus to the anterior abdominal wall. The new point in the operation which he would recommend was the introduction of the index finger into the bladder in order to facilitate the application of the sutures fixing the bladder, and to estimate definitely the correct depth these sutures should take in the bladder wall. Incontinence never lasted over a day or two, and if cystitis occurred, "a couple of silver-nitrate injections would dispose of that."

---

## Surgical Suggestions.

**Shock.** — No operation should be performed on a patient in the condition of shock, unless there be actual bleeding endangering life, and even then chloroform should not be administered. I cannot accept the dictum that complete anæsthesia protects against shock. —Cheyne.

**Plastic Operations and Kidney Disease.**—A plastic operation is unjustifiable in a subject of kidney disease. The operation wound is liable to break down, to suppurate, and be the seat of secondary hemorrhage, of erysipelas, of cellulitis, and even of gangrene. When pyæmia is common in hospital wards, the subject of kidney disease becomes its readiest victim. Surgeons have learned how to ward off pyæmia, but they have yet to learn how to meet the complications of Bright's disease.—Frederick Treves.

**Influence of Tuberculosis upon Injuries.**—On the questions of operations upon the subjects of actual and active phthisis Sir James Paget writes as follows: "The fever and other accidents which may follow an operation may do special harm to a tuberculous patient. . . . The fear of such a calamity should dissuade you from all operations of mere convenience, and from all measures of what may be called decorative surgery in phthisical people; but it should not always dissuade you from operations that will cure diseases from which they suffer much, and by which their lives are wasted, as they are by fistula and diseases of the bones and joints. In these and the like cases the main question is whether the local disease—say, a diseased joint—is weighing on the patient so heavily or aggravating his phthisis and shortening his life so much as to justify an operation attended

with more than the ordinary risk of life and health. In all cases of acute or progressive phthisis great risk is incurred by almost every operation. . . . The case is very different with chronic or suspended phthisis. In these it is often advisable to incur the somewhat increased risk of even a large operation, in order to free the patient from the distress and wasting of a considerable local disease, such as that of a joint; and I should be disposed to say that it is always advisable to cure, if you can, a small disease such as fistula. I say if you can, for you will often be disappointed."

**Injection in Hemorrhoids.**—Internal piles suitable for the injection method may be injected with:

℞ Acid. carbolic..... ʒ iss.
Acid. salicylic..... ʒ ss.
Sodæ biboratis..... ʒ i.

M. ft. solutio.

Two to four minims to be injected into the base of the hemorrhoid. If other injections are required, they are made in from three to five days.—Tuttle.

**Burns.**—Picric dressing should not be considered as a wet dressing, for in cases of burns wet dressings should be absolutely excluded. Immersion of the parts in a bath of picric acid, followed by a light cotton-wadding dressing, is the best method when it can be applied. The application of any greasy substances to burns should be avoided on all occasions.—Théry.

**Internal Urethrotomy.**—If you cut at all, cut all.—Sir Henry Thompson.

I regard internal urethrotomy, when properly performed, as one of the most useful and successful operations in surgery.—P. J. Freyer.

My firm conviction is that the operation of internal urethrotomy will gradually become less frequent until it finally disappears from the list of recognized surgical procedures.—Myles, quoted in *The Medical Press and Circular*, December 21, 1898.

**Dressing for Fracture of the Os Calcis.**—Having looked in vain for specific directions in the treatment of a fracture of the "heel," or os calcis, the following is submitted: A roller bandage three inches wide and five yards long is all that is necessary. Starting with two turns above the toes, the roller is carried diagonally over the instep, covering the external malleolus, behind and below the internal malleolus to the sole of the foot, pulling the fragment down; then passing over the outer side of the foot diagonally across the instep, covering the internal malleolus, behind and below the external malleolus to the sole of the foot again, dragging the fragment down, but in the opposite direction from the first turn. A repetition of these turns as may be necessary is all that is required to keep the parts immobile until union takes place.—A. M. Whiton, *South Byron, N. Y.*

**Surgical Treatment of Goitre.**—Dr. Jules Boeckel (*Gaz. Méd. de Strasbourg*, February 1st) concludes that thyroidectomy is a benign operation; the mortality being scarcely four per cent. The most formidable accidents are hemorrhage and collapse of the trachea—both are followed by death. These two factors are the only ones that cast doubt on the prognosis, for in our day phlebitis of the neck, mediastinal fistula, etc., ought not to enter into consideration. Out of seventy-four thyroidectomies, twenty-five partial, two total, and forty-seven enucleations, there were six deaths, one of which was due to the falling of a piece of laryngeal polyp into the bronchi; three deaths were caused by hemorrhage, and two by collapse of the trachea. The sequelæ of the operation are in general benign. Out of sixty-eight cases cured, forty-five healed by first intention in from five to nine days; five similar cures with the formation of a fistula after cicatrization with entire cure in from two to six weeks; twelve cases with fistula and slight suppuration; two cases of suppuration in cases of suppurating thyroiditis; one case of cure by grafting in a thyroidectomy preceded by tracheotomy. The secondary accidents were three cases of hemorrhage that could be easily controlled, and two cases of tetanus that were cured within a reasonable length of time. Intracapsular enucleation is preferable to partial extirpation. In cysts this is an operation of choice, but in parenchymatous goitres it ought always to be practised when possible.

**Actinomycosis of the Lungs.**—The medicinal treatment of actinomycosis of the lungs is symptomatic only. Large doses of iodide of potassium (gr. xx.-xl. three times a day) are recommended, but it is doubtful if it does any real good. Surgical measures are the only means that may avail against the inevitably fatal results, and on this account much greater risk may be assumed than is justifiable in other pulmonary diseases. We must bear in mind the great danger of hemorrhage during operation, and also the possibility that the disease has extended to places and tissues where surgical intervention cannot follow.—John M. Patton.

**Whitehead's Operation for Hemorrhoids.**—Dr. S. G. Gant (*Kansas City Medical Index-Lancet*, May) criticises this operation as follows: (1) It is not suited for ordinary or bad cases of piles. (2) It is difficult and bloody. (3) Patients are detained in bed from six to fifteen days longer than after the clamp-and-cautery or ligature operation. (4) Owing to tension, the post-operative pains are severe and may continue for several days. (5) Infection is frequent and terminates in a stitch or deep abscess and fistula. (6) Because non-union, ulceration, stricture, and pruritus are common sequelæ. (7) The portion of the bowel between the anus and the end of the retracted intestine loses its sensitiveness, and there is also an absence of the normal secretions. (8) The nervous and mental state of these sufferers is pitiable to behold, and many contract the morphine habit, while others turn up as chronic invalids in some sanatorium or asylum.

**Rectal Don'ts.**—(1) Don't venture a diagnosis until after a careful examination. (2) Don't turn a speculum while it is in the rectum, and you will avoid much pain. (3) Don't force the finger or speculum into the bowel; wait until the sphincter becomes accustomed to it by gradual pressure, and it will slip in. (4) Don't go into details when explaining the technique of an operation to a patient. (5) Don't fail to operate at the earliest opportunity; your patient may change his mind. (6) Don't omit to prepare your patient for operation, and opium will not be required to tie up the bowel. (7) Don't use suppositories for post-operative pain; relieve it promptly by hypodermic injection. (8) Don't fail to move the bowel on the third or fourth day, or impaction and severe pain will follow. (9) Don't give solid food for the first few days. (10) Don't mistake hemorrhoids, polypi, and prolapsus, the one for the other. (11) Don't use mechanical dilators; the fingers are better and less dangerous. (12) Don't sever the sphincter obliquely, but at a right angle. (13) Don't agree to cure pruritus ani or a cicatricial-tissue stricture within a specified time, and embarrassment will be prevented. (14) Don't divide the sphincter but once in multiple fistula; make the branch sinuses communicate externally with each other and with the rectum by the main tract. (15)

Don't pack the wound following an operation for fistula too tightly, or granulation will be arrested. (16) Don't forget to inform your patient that incontinence is a possibility under the most favorable circumstances. (17) Don't operate for fistula on patients suffering with acute phthisis or acute Bright's disease. (18) Don't keep patients suffering from tuberculous fistula in the house, but give them the benefit of sunshine. (19) Don't fail to divide all branch sinuses, otherwise a second operation will be required. (20) Ligate or twist all bleeding vessels.—S. G. Gant, in *The Medical Fortnightly*, May 15th.

**Rachitic Deformities.**—In cases of knock-knee and bow-legs, when the deformity has been corrected either by manipulation or osteotomy, it is often advisable for the child to wear a slight supporting brace, for the purpose of preventing return of the deformity, and to this end I think that instruments with joints are as useful as I have found them useless in the correction of deformity.—Reginald H. Sayre.

**Venereal Arthropathies.**—Many of the cases of acute synovitis of adults are gonorrhœal and should be subjected to aspiration, irrigation, and iodoform or arthrotomy. Many of the cases of epiphysitis of adults are associated with secondary syphilis, and should receive mercurous iodide; when associated with tertiary syphilis, they should receive potassium iodide; in neither condition should the knife be used. In many cases of hip-joint and Pott's disease, and other bone-diseases of children, the patients are suffering from hereditary syphilis, and should be given iodides. In all cases of so-called bone disease and joint disease potassium iodide should be administered, whether a specific history can be obtained or not.—McCurdy.

## Correspondence.

### OUR LONDON LETTER.

(From our Special Correspondent.)

EMPTY LONDON — SECRET COMMISSIONS, RENEWED ACCUSATION — PHARMACOLOGY — HEAT WAVES AND STORMS — NEWCASTLE INFIRMARY — TYPHOID AT FALMOUTH—DR. FARQUHARSON, M.P.—LONDON HOSPITAL.

London, September 8, 1899.

The emptiness of London is a common expression just now, and in some circles there is a kind of excuse for it. So large a number of our consultants and teachers are away that now and then it is not an easy matter to secure a second opinion. The other day a surgeon spent two hours looking for a physician—and this in the Cavendish district which is so much frequented by doctors. Many he went for were away, but, of course, there were some remaining. Eventually he found one at home, but not one of his acquaintance. This dearth of doctors does not extend to general practitioners. Though a proportion of these are also taking a holiday, they mostly provide a *locum tenens* to take care of their patients during their absence, and even when they do not there is never any difficulty in finding a disengaged G. P., for the overcrowding of the profession increases continually.

*The Times* has provided us with a sensation this week by publishing a letter from Sir Edward Fry, reiterating the charge against the medical profession of taking secret commissions. This charge was made first by the Chamber of Commerce, and you may remember that Sir Edward Fry wrote to *The Times*, in 1896, a letter in which he descended to depicting a young doctor computing at the bedside the comparative advantage to himself of the patient living to pay future fees, or dying and thereby giving him a commission from the undertaker. Indignation was naturally expressed and evidence called for. The British Medical Association made an application for such evidence. But nothing has been produced, save the assertions of two anonymous persons—a chemist and an optician—and their anonymity is carefully preserved by the Chamber of Commerce, as the statements were made under a promise of secrecy. The council of the association made its own inquiry, and reported to the Portsmouth meeting that there was not ground for such an accusation, and asked the Chamber of Commerce to substantiate. A resolution to this effect was adopted, and now Sir E. Fry returns to the charge and accuses the council of trying "to hamper the chamber in its effort after honesty."

Well has the president of the council said that this is a gross travesty of the facts. Sir Edward Fry wants to know who made the inquiries of the council, who and how many were they, and goes on to repeat his disgraceful accusations. Perhaps the most disgraceful thing about this matter is his own assertion on the strength of his "secret dossier," for Sir Edward Fry has been a judge. On his retirement he seems to have left behind him all sense of the judicial attitude and taken up the position of an advocate. It is possible, no doubt, that here and there among the thirty thousand doctors some one may prove himself unworthy of the profession. In fact, the medical council has had to expel some. But that is no worse than Sir Edward Fry's own profession, in which only last week one was condemned to penal servitude. How would Sir Edward like a charge to be made thereupon that the legal profession is generally dishonest?

Professor Bradbury did well to draw attention at Portsmouth to the unsatisfactory position of pharmacology in the curriculum. He would place it beside pathology. No one can doubt that the coming generation of practitioners will be badly equipped in regard to this subject, and I often meet with younger men who are scarcely able to write a good prescription. The pharmacist is ready enough to help, and the manufacturers are continually thrusting upon us their wares of pills, tablets, and other preparations. By these men are saved the trouble of dispensing or considering dosage. But what a reversal of the position of physician and apothecary! The modern chemist affects to supply the doctor's deficient information! Are we likely to have a reaction against ready-made pharmacy? The old days of apprenticeship secured a better knowledge of drugs and the mode of administering them than is common to the newly fledged graduate of to-day. In this respect those who advocate that part of the fifth year might well be spent with a senior practitioner have reason on their side, but, alas, too many of such practitioners have already fallen into the idle plan of trusting in ready-made remedies.

The heat wave returned at the beginning of the week, and the thermometer rose to 90° F. again, causing considerable discomfort and a further increase of infantile diarrhœa and other diseases. These sudden changes almost always affect the mortality, but have a still greater influence on non-fatal cases, which are very prevalent just now.

On Wednesday a violent thunderstorm came on with an extraordinary downpour, flooding the streets and not a few buildings. Although the rainfall lasted only about half an hour it amounted to as much as one inch as measured at the meteorological office. The thermometer fell during the storm about ten degrees. Havoc was wrought by the impossibility of the sewers' carrying away the water fast enough. They can cope with an inch of rain in a day—but in an hour! The

demand was unprecedented. Storms have also been prevalent in the provinces, and to the tale of deaths from heat-stroke must be added those from lightning.

Newcastle is to have a new hospital to replace the Royal Infirmary. Mr. R. Lord was the mayor in 1897, the year of the Queen's Jubilee, and proposed to raise £60,000, being £1,000 for each year of the Queen's reign, to rebuild the infirmary. The response was so generous that no less than £100,000 was promptly promised. Recently another £100,000 bequeathed by Mr. Hall, J., has become available, and it is expected that the foundation stone of the new building will be laid in a few months' time.

Falmouth has suffered for some time from typhoid, which is now epidemic. Nearly one hundred cases have occurred during the summer. The disease has recurred from year to year, and it looks as if the sanitary authorities are not so active as they might be. In the month of August there were forty fresh cases. The neighboring borough of Penrhyn has appealed to the local government board to decide how it can deal with the water company which supplies both boroughs. One of the reservoirs has been condemned by the district council.

Dr. Farquharson, M.P., has met with an accident which might have been serious. While distributing the prizes at a horticultural show on Wednesday, the platform suddenly collapsed. Several persons were bruised and shaken. The doctor escaped with a slight injury to his knee.

The London Hospital comes in for £10,000 from Mr. Raphael toward endowing a new ward, and £60,000 from the late Baroness de Stern toward a convalescent home.

## LA SOUDANITE.

To the Editor of the Medical Record.

Sir: The shocking news of the murder of Lieutenant-Colonel Klobb, Lieutenant Meynier, and eight soldiers by Captains Chanoine and Voulet of the French army, brings before our attention a peculiar species of mental aberration known to African explorers and military men.

"La Soudanite" is the name given to a form of insanity supposed to be caused by the tropical heat. The French describe it as setting in with ennui and mild fever, marked with anæmia. A moral and mental fever (*fièvre morale*) soon follows, assuming different phases in different individuals. A camp may be disturbed before dawn by repeated pistol-shots, and an investigation will find one of the party amusing himself by repeatedly firing at small objects—la Soudanite. Or, one may insist on going clothed in dark and heavy stuffs in spite of the heat, because others "let in the light"—la Soudanite. An entire company may find itself given over to senseless disputation, at which hours are wasted—la Soudanite, etc. Contrariness is perhaps its distinguishing characteristic, associated with a marked spirit of intolerance.

The disease is known in Africa only, and recalling the peculiar phases malarial diseases assume in the tropics, we are inclined to believe that this is probably a malarial manifestation. French military men who have experienced the disease claim that it is modified by quinine and practically entirely overcome by work—constant work. Since it is the custom for military and exploring parties to use quinine constantly in those climates, it may be that there is brought about a sufficient amount of cerebral irritation by the drug to account for the manifestations.

It seems clear that the unfortunate Captains Chanoine and Voulet, and the men under them, were victims of the *fièvre morale*, which led them not only to acts of insubordination but to actual murder. It is to be hoped that fuller particulars will be given, so that the real cause and nature of the curious malady may become known.

W. J. Greanellé, M.D.

University Heights, New York City

## CANCER STATISTICS.

To the Editor of the Medical Record.

Sir: I recently wrote to the London *Lancet* to protest against the attempt, both here and in England, to create a "cancer scare." I showed, beyond doubt, that some of the figures given in the "cancer number" of *The Practitioner* by a distinguished American surgeon were wrong, and that his conclusions were unsupported by reliable evidence. *The Lancet* did not publish my letter because "it is against our rule to publish letters on strictly medical subjects from non-medical writers"; but on August 26th it printed what is, in reality, a criticism of my communication. In the circumstances, I am anxious to draw the attention of the medical profession in this country to a recent investigation of cancer statistics which cannot, on account of its length, be reproduced here. I refer to a paper by Mr. King, of London (a prominent actuary), and Dr. Newsholme, published in the Proceedings of the Royal Society, vol. liv., p. 209. The paper is entitled "On the Alleged Increase of Cancer." I would also draw attention to Dr. Newsholme's new book[1] on "Vital Statistics" (Macmillan, New York, 1899), in which he gives his reasons for asserting that the increase in cancer is "only apparent."

American statistics do not date far enough back to give any very valuable information; and when the English figures from 1858 to 1897 are used with the necessary explanations and with proper discretion, they do not prove any remarkable increase in the cancer death rate.

The articles in *The Lancet* of April 22d and May 20th, of this year, received careful consideration from me at the time of their publication; but the writer of them had evidently not read Dr. Newsholme's paper, already referred to, which effectually disposes of *The Lancet's* statements.

Althought *The Lancet* did not print my letter, because I am a layman, it nevertheless inserted a communication upon the position of the antivaccinators, from a gentleman who does not belong to the medical profession, in the identical issue (August 26th) in which its reasons for the non-insertion of my epistle were contained! Presumably, therefore, statistics are "strictly medical subjects," but antivaccination is not a purely medical question. However this may be, I protest against a criticism of my assertions when my letter is not published, and when it is made evident that any reply which I may make will not appear in print.

Upon the few occasions on which I have requested medical journals to publish letters from me, the subject matter has invariably been either statistics or heredity, neither of which is the exclusive province of the medical profession. Indeed, the average physician is deplorably ignorant of the latter and takes little interest in the former.

Lawrence Irwell, M.A., B.C.L.

Buffalo, N. Y.

**Appendicitis.**—Personally I would allow my junior assistant on the hospital staff to operate upon me for appendicitis, rather than try the best medical treatment for one day.—Robert T. Morris.

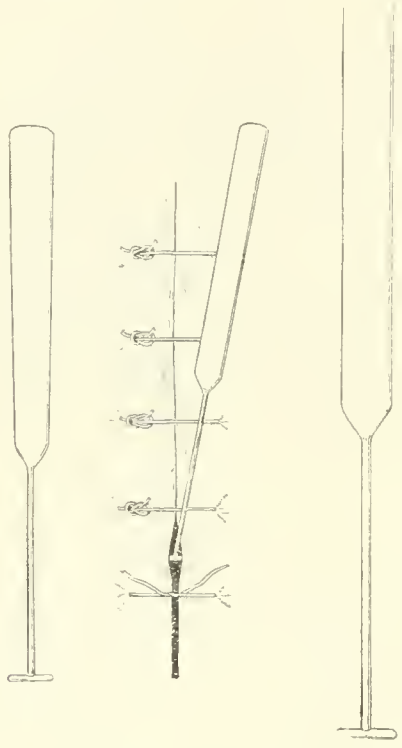
## New Instruments.

### AN ADJUSTER FOR USE IN THE CLOSING OF WOUNDS.

By CEPHAS L. BARD, M.D.,
VENTURA, CAL.

Aseptic and cosmetic considerations demand a perfect coaptation of the edges of a wound. That its accomplishment, especially in certain regions where lax tissue exists, is not always easy is well known, particularly to the occasional operator. Both in the interrupted and continuous suture, there is usually noticed a tendency of one edge to overlap the other. To obviate it the unassisted surgeon, after placing his sutures, inserts the handle of his scalpel, or some other suitable instrument, into the line of incision, with the result generally of elevating one and depressing the



other edge. When he is provided with an assistant, the edges are nicely held together by the grasp of two tissue forceps, but the practice, while meeting the requirements, is objectionable, as the tissues are injured by the bite of the instruments, and their vitality is diminished.

A better way will be found in the use of the simple adjuster shown in the illustration, which on account of its utility, compactness, and cheapness merits a place in the instrument case of every surgeon. It is made of a single piece of nickel-plated steel, and consists of a T-shaped shank continuous with a flat handle, which latter serves also as a dry dissector. It is inserted with the bar parallel with the wound, and a quarter turn on its axis places it in position, the bar at the extremity of the shank being at right angles with the incision. Traction on it prevents any inversion or eversion of the edges of the wound and brings them into perfect apposition. Its removal is effected by a quarter turn reverse to that of its introduction. The position of the handle indicates that of the bar beneath the integument. When interrupted stitches are used, it can be applied either in advance or in the rear of the suture which is being placed. In the continuous suture, it should be used in front of the insertion of the stitches.

## Medical Items.

**Contagious Diseases—Weekly Statement.**—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending September 23, 1899:

| | Cases. | Deaths. |
|---|---|---|
| Tuberculosis | 106 | 128 |
| Typhoid fever | 85 | 19 |
| Scarlet fever | 80 | 4 |
| Measles | 55 | 7 |
| Diphtheria | 145 | 26 |
| Laryngeal diphtheria (croup) | 5 | 6 |
| Cerebro-spinal meningitis | 0 | 9 |
| Chicken-pox | 4 | 0 |

**Dentistry for School Children.**—At the British Sanitary Congress, recently held at Southampton, Mr. S. Spokes read a paper on the treatment of the teeth during school life, and submitted the following suggestions: (1) That in all poor-law schools dental treatment should be compulsory; (2) that in board schools it should be at first optional and later on obligatory; (3) that in boarding-schools there should be compulsory inspection on arrival, with reports to parents when necessary. Treatment would, of course, be optional, but parents should be requested to arrange for periodical inspection and a visit to the home dentist in sufficient time before the end of the vacation to allow for any treatment necessary. (4) That for all scholars the use of the tooth-brush after the last meal of the day should be enforced.—*Sanitary Record.*

**The Value of General Symptoms.**—"I well remember my first case of pneumonia when I started practice, and how I hurried home to tell my father with a certain amount of pride what I considered a more or less definite piece of physical diagnosis. My father paid little attention to my recounting the extent of dulness and the characters of the respiratory sounds, and more or less abruptly broke in with the simple question, 'What are his general symptoms?' and then started a cross-examination as to his general expression, color of skin, clearness of mind, amount of sleep and length of uninterrupted sleep, how he had taken his nourishment, the amount of urine he had passed and its condition, and on hearing my answers gave me a prognosis diametrically opposite to the one which my physical diagnosis had led me to believe. And he was right. He taught me a lesson which has stood me in good stead."—Dr. L. A. Weatherly.

**Domestic Animals and Preventive Medicine.**—In preventive medicine and hygiene the domestic animals have served as the basis for study and investigation. At the close of the last century Jenner's application of cowpox as a protection against smallpox led to the almost complete expulsion of that once-dreaded scourge from civilized lands. Pasteur in 1866 pointed out the need of cleanliness, fresh air, and good food for the avoidance of degeneration and disease in the silkworms; and are not these the foundation stones of hygiene for all animal forms? In silkworms Pasteur also found causes for disease in the microscopic organisms which infested their bodies; and in some cases this cause appeared to pass from one generation to the next through the eggs. What this study of Pasteur upon diseases of silkworms, upon anthrax in the domestic mammals, and upon fermentation did for surgery is thus expressed by Lister, the recognized fa-

ther of antiseptic surgery, at the jubilee celebration of Pasteur: "Truly, there does not exist in the entire world any individual to whom medical science owes more than to you. Your researches on fermentation have thrown a powerful beam which has lighted the baleful darkness of surgery and has transformed the treatment of wounds from a matter of uncertain and too often disastrous empiricism into a scientific art of sure beneficence. Thanks to you, surgery has undergone a complete revolution which has deprived it of its terrors and has extended almost without limit its efficacious power."—*Scientific American Supplement.*

**"Getting into Condition."**—The systematic practice of athletics, especially that involved in the process of what is termed "getting into condition," develops a necessity for muscular labor that is somewhat disastrous. I find that I am the lucky possessor of a uric-acid diathesis, which at times gives considerable annoyance and which I would gladly avoid as a matter of economy of time. I find that I have acquired a demand for a large amount of nitrogenized food, but so soon as I cease systematic exercise the capacity for assimilation of proteids is so seriously impaired that one of my occasional crises of lithæmia is at once precipitated. I can assure any one who contemplates entering active training that he will in time acquire thereby a physiological habit that may be a little embarrassing later in life, and I would seriously advise all would-be athletes against getting into so-called perfect condition.—Dr. Frank Lydston, *Medical Mirror*, September.

**Prevention of Lead Poisoning.**—The final report of the departmental committee appointed to inquire into and report upon certain miscellaneous dangerous trades in Great Britain has just been issued. In reference to peril to life and health attending the use of lead the report says that the use of lead in various forms in print and dye necessitated an exhaustive inquiry in regard to yarn dyeing and calico printing. Into some of the processes lead enters to a considerable degree, although in certain factories the committee noted that manufacturers were adopting aniline or vegetable dyes, by which practically the same colors were produced. The existing special rules are limited to works in which yellow chromate of lead is either made or manipulated, and have no application to departments where either green or lemon colors are prepared or handled. For those now in use the committee recommended the substitution of the following rules, which they say apply to all the processes mentioned in the existing rules as regards the yellow and orange colors: (1) No young person should be employed. (2) The occupier should supply overalls and head covering, and should have them thoroughly washed not less than once a week. (3) No food should be eaten by any one in a room in which yarn colored with yellow or orange chromate of lead is bundled or noddled, reeled, wound, woven, or otherwise treated. (4) The occupier should provide and maintain a sufficient and suitable supply of washing conveniences fitted with basins, in the proportion of one to every five or fraction of five persons employed. (5) The occupier should set apart and enter in the notice a period of at least five minutes in addition to the regular meal-times for washing immediately before each meal-time, and also before the end of each day's work, and he should see that it is observed. (6) The occupier should take measures to secure that each person engaged in any of these processes washes his or her hands and face before meals and before leaving the works. (7) Hoods or cowls should be provided opposite or close to the bar upon which the yarn is noddled, and should be so constructed that the draught from a fan shall draw the dust away from the face of the worker. (8) The occupier should see that no person be employed or re-employed after absence through illness, without a certificate from the certifying surgeon. (9) All persons employed in these processes should be examined once a month by the certifying surgeon, who shall enter the result of each examination, and any recommendations, in the prescribed register. He shall have power to order temporary or total suspension. (10) The occupier should provide a sufficient supply of sanitary drink and should cause the work-people to take it.

**Russian Weights and Measures** are the subject of a new regulation recently officially published. The Russian pound is fixed as the standard of weight and declared to be equal to 409.512 gm.; a pail or vedro is to hold thirty pounds of distilled water at $16\frac{2}{3}^{\circ}$ (Celsius), and a garnietz eight pounds of water. The unit of length is the arshin, equal to 71.12 cm. The metric system is to be optional, and may be used on a par with the Russian in commerce in dealing with contracts, accounts, etc., and after mutual agreement by state and municipal authorities. Private persons, however, are to be under no compulsion to use the metric system when dealing with the above-named authorities.

**Intemperance a Factor in the Causation of Crime.**—An important factor in the causation of crime is intemperance. Fully fifty per cent. of the criminals arrested in Chicago are inebriates, and the police reports of New York show about the same proportion. As Macdonald has well expressed it, "The saloon is the place where criminals find their accomplices. It is the abode where they not only meditate their crimes, but where they spend the money obtained by crime. The saloon is the true home of the criminal, and sometimes the keeper plays as backer." Ferri has shown beyond question that in France crime increases and decreases with the more or less abundant vintage, and we may safely attribute at least some of the increase of criminality and pauperism in the United States to the increase of intemperance; and we may estimate that alcoholics are the direct or indirect cause of probably seventy-five per cent. of the crimes committed.—Dr. Daniel R. Brewer.

**Danger in Licking Postage Stamps.**—The English *Pharmaceutical Journal* says: "The danger of licking postage stamps was the subject of much comment in the English daily press some time ago, and the adhesive matter upon the stamps was blamed for causing serious trouble at times. But while it is undoubtedly better not to lick postage stamps with the tongue, the gum upon them has now been vindicated against the charges made against it. It has been submitted to the government laboratory for analysis, and, as *The Daily News* expresses the result, it has left that institution without a stain upon its character other than the chemicals employed in testing." It had been alleged that the gum had occasioned septicæmia in a particular case, but Dr. Thorpe, the principal government chemist, reports that "bacteriological cultivations were made both from the stamp paper and the gum employed as the adhesive material, but no pathogenic organism could be detected in either case." At the same time, as the *Daily News* suggests, one cannot employ similar tests to everything with which the stamp paper may come in contact. One cannot make bacteriological cultivations from the drawers of old post-offices or from the fingers of the counter clerks.

**Typhoid Fever in the British Indian Army.** In 1897 this disease caused 2,050 admissions, 556 deaths, and a constant sickness of 296.85, being in the ratio of 31.8, 8.62, and 4.60 per 1,000 respectively. The

significance of these figures can be gauged only by comparison. The *Sanitary Record* says that the total number of deaths among the British troops in India in 1897 was between 1,200 and 1,300, and of these 556 were due to enteric fever. No other specific disease caused as many as 100 deaths, though 116 are recorded as due to diseases of the digestive organs. In several stations in India typhoid fever is now admitted to be endemic. The seasons when it is ordinarily most prevalent are in April and May and in November and December. The consensus of medical opinion points to the probability that the troops contract typhoid fever not in barracks, where they live under the most careful sanitary supervision and surroundings, but in the native drink-shops and other objectionable institutions. As regards the influence of age and service in India upon the incidence of the disease, by far the greater number both of admissions and deaths occur among men from twenty to twenty-five years of age and upward, who have been less than one year in the country. Only four admissions and two deaths occurred among some eighteen hundred men aged between thirty-five and forty years, and only three admissions and one death among nearly two thousand men who had been in India upward of ten years.

**Grant in Great Britain for a National Physical Laboratory.**—The British Parliament has sanctioned a grant of $60,000 for a national physical laboratory, with an annual appropriation of $20,000, and Mr. R. F. Glazebrook, now principal of University College, Liverpool, has been appointed director. The establishment of the laboratory is due to action on the part of the British Association.—*Science.*

**What is Good Meat?**—Poisoning by alimentary substances is so frequent, and the grave symptoms following the ingestion of tainted food are often so transitory, that their causes elude detection. Recently it has been proposed to make use of the clumping reactions made familiar by the Widal test, to determine the bacillæmic qualities of meat, and it would seem that the method promises much. It may be wise to recall a few of the characteristics of sound meat. Good, wholesome meat is neither of a pale pinkish nor of a deep purple tint. It has a marbled appearance, from the ramification of little veins or intercellular fat; the fat of the internal organs especially is firm, hard, and suety, and is never wet; whereas that of diseased animals is often soft and watery. Good meat has but little odor, whereas diseased meat smells faint and cadaverous. Good meat bears cooking without much shrinking or losing much of its weight, but bad meat shrivels up and boils to pieces—this being due to the larger proportion of watery and gelatinous material and the absence of true muscular substance. Under the microscope the fibre should be clear and well defined and free from infusorial animalculæ, while that of diseased meat is sodden as if it had been soaked in water; the transverse streaks are indistinct and wide apart, and animalculæ abound in it.—*Sanitary Record.*

**The Discovery of Trichina.**—In 1833 James Paget, interne in a London hospital, while dissecting the muscular tissues of a human subject, found little specks of extraneous matter which when taken to the professor of comparative anatomy, Richard Owen, were ascertained with the aid of a microscope to be the cocoon of a minute and hitherto unknown insect. Owen named the insect "Trichina spiralis." After the discovery was published it transpired that similar specks had been observed by several earlier investigators, but no one had previously suspected, or at any rate demonstrated, their nature. Nor was the full story of the trichina made out for a long time after Owen's discovery. It was not until 1847 that the American anatomist, Dr. Joseph Leidy, found the cysts of trichinæ in the tissues of pork; and another decade or so elapsed after that before German workers, chief among whom were Leuckart, Virchow, and Zenker, proved that the parasite gets into the human system through ingestion of infected pork, and that it causes a definite set of symptoms of disease which hitherto had been mistaken for rheumatism, typhoid fever, and other maladies. Then the medical world was agog for a time over the subject of trichinæ; government inspection of pork was established in some parts of Germany; American pork was excluded altogether from France; and the whole subject thus came prominently to public attention. But important as the trichina parasite proved on its own account, in the end its greatest importance, after all, was in the share it played in directing attention at the time of its discovery, in 1833, to the subject of microscopic parasites in general.—*Harpers' Magazine.*

**Paris Water Supply.**—The Paris water authorities issue a note of warning to consumers. They point out that, in spite of the excessive heat which has been experienced, they have had no difficulty in maintaining the supply of drinking-water at its usual quantity. But during the last few weeks the consumption has been increasing in a larger degree than can be accounted for by the increased thirst of the Parisian population, and consumers are therefore asked not to use the drinking-water for ordinary watering, but to restrict its use to domestic purposes. The request seems reasonable. A London water company would cut down the supply and make sure of it. It is to be hoped that the Parisian authorities will not be driven to the extreme measure of turning on the Seine water. —*Pharmaceutical Journal.*

**Health Reports.**—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended September 23, 1899:

| | | Cases. | Deaths. |
|---|---|---|---|
| **Yellow Fever—United States.** | | | |
| Florida, Key West | September 13th to 19th | 164 | 7 |
| Louisiana, New Orleans | September 2d to 15th | 15 | 2 |
| **Smallpox—United States.** | | | |
| Massachusetts, Fall River | September 2d to 9th | 1 | |
| Michigan, Battle Creek | September 8th to 16th | Present. | |
| Maple Grove | September 8th to 16th | Present. | |
| Ohio, Cincinnati | September 2d to 9th | 5 | |
| Pennsylvania, Allegheny | August 29th to September 2d | 2 | |
| **Yellow Fever Foreign.** | | | |
| Brazil, Bahia | August 20th to September 2d | 10 | 8 |
| Colombia, Barranquilla | August 12th to 27th | 1 | 1 |
| Colon | August 20th to September 3d | 1 | 1 |
| Panama | September 5th to 12th | 8 | 3 |
| Port Limon | August 20th | 1 | |
| Cuba, Havana | September 3d to 10th | 24 | 3 |
| Nuevitas | September 2d | 1 | |
| Santiago | August 29th to September 5th | 3 | |
| Mexico, Tampico | September 8th to 11th | 2 | 1 |
| Tuxpan | August 26th to September 4th | .. | 2 |
| Vera Cruz | September 1st to 14th | .. | 21 |
| **Smallpox—Foreign.** | | | |
| Belgium, Antwerp | August 19th to 26th | 3 | |
| Brazil, Rio de Janeiro | July 21st to 28th | 54 | 24 |
| Cuba, Manzanillo | September 4th | Several cases. | |
| Egypt, Cairo | August 11th to 19th | 4 | |
| Greece, Athens | August 22d to September 2d | 14 | 3 |
| India, Bombay | August 8th to 15th | 11 | |
| Mexico, Chihuahua | August 28th to September 9th | .. | 11 |
| Mexico | August 13th to 27th | 9 | 6 |
| Russia, Moscow | August 12th to 26th | 4 | 1 |
| Odessa | August 19th to 26th | 1 | 1 |
| St. Petersburg | August 19th to September 2d | 11 | 4 |
| Warsaw | August 12th to 26th | .. | 3 |
| Straits Settlements, Singapore | July 29th to August 5th | .. | 1 |
| **Cholera.** | | | |
| India, Bombay | August 8th to 15th | .. | 1 |
| Calcutta | July 30th to August 5th | .. | 57 |
| **Plague.** | | | |

### ON SOME IMPORTANT POINTS REGARDING PERFECTION OF ASEPSIS.[1]

BY CARL BECK, M.D.,

NEW YORK.

THE best proof that the treatment of a given disease is imperfect is furnished by the large number of different drugs recommended in that treatment. The prevention of sepsis is by no means an exception to the rule.

The number of powerful drugs advertised as reliable germ-killers is legion. The description of different protective methods, all more or less ingeniously devised, would fill a small library. Some of these devices furnish most brilliant testimony to the unselfish, even the martyr mood of their inventors, and are indeed so radical that, if they were carried out to their final consequences, not only the bacteria adhering to the surgeon would be entirely destroyed, but of the surgeon himself hardly anything more than the bones would be left.

The factors which may interfere with asepsis are the instruments, the dressing and suture material on the one hand, and on the other the atmosphere and the skin of the patient and of the surgeon's hands. In reference to the first factors it can safely be maintained that ideal asepsis is now an established fact. All objects which stand boiling well can indisputably be made sterile. This also applies to the much-disputed question of catgut, since Hofmeister has shown us by the former line of treatment how to boil this material without impairing its tensile strength.

It is, of course, to be presumed that the sterilization of the material in question is supervised by the surgeon himself. The process of sterilization must, in other words, go on in the operating-room, where the sterilizers must be kept. There the towels, dressings, the suture material, etc., must be taken from the sterilizer and put directly upon the instrument-table or the body of the patient. This naturally causes trouble for the surgeon, but it is an absolute necessity, in view of that fatal human characteristic—forgetfulness.

The second factor, the atmospheric, seemed to have been settled by the classical experiments of Schimmelbusch, Petri, and Cleves-Symmer. But in consequence of Fluegge's investigations[2] this question has been revived recently, and it seems to have disturbed the surgical mind unnecessarily. Theoretically the possibility of atmospheric infection cannot be disputed. But it hardly is attainable in practice. The atmosphere, it is true, contains an enormous number of bacteria, but these being innocent mould, yeast, and fission fungi, they are fortunately non-pathogenic for the human race. Bacteria which are pathogenic for man are present in the atmosphere only under abnormal conditions, as, for example, when they are stirred up from their natural habitat, the earth's surface or the dust of the walls, the floor, the tables, etc. The properties of the atmosphere are, in fact, injurious to pathogenic bacteria in every respect. The atmosphere, if exceptionally visited by a vagabond pathogenic bacterium, can be only a temporary and most uncongenial halting-place for it, in which it will soon be destroyed. It is a most fortunate feature of the pathogenic bacteria, especially the pus-producing variety, that they have a marked tendency to settle. Wherever they settle they use to adhere and if they are not provoked, so to say, by being stirred up, they cannot come into contact with a wound.

According to Stern's experiments heavy bacteria settle to the ground within the course of an hour and a half, while the lighter ones require about an hour longer.

From these facts we learn that the bacteria-containing dust in a room should not be stirred up by cleaning and sweeping a few hours before an operation is to take place there. As moisture precipitates dust, it is advisable to saturate the air in the operating-room at least during two hours before the operation. This can be done by filling the air with spray or with steam from a kettle. The windows should also be kept closed, especially if there is a current of wind directed toward the windows.

But another possible source of infection propagated by the atmosphere deserves attention. The air expired by the healthy, according to Tyndall, does not contain bacteria, although the cavity of the mouth is a well-known gathering-place for all kinds of pathogenic as well as non-pathogenic bacteria. Staphylococcus and streptococcus are nearly always found. It has, however, been proven by bacteriological test that in healthy persons the virulence of these bacteria is very slight. Clinical observation is in accord with this. But if the surgeon suffers from tonsillitis or even from a rhinitis, the number as well as the virulence of his intra-oral bacteria is remarkably increased. If the sick surgeon talks and coughs a great deal while bent over the wound, there is a possibility of carrying some of these bacteria into it, especially in an operation of long duration. The remedy is simple and proves the wisdom of the old saying, "Speech is silver and silence is gold."

The assistants in the operating-room must be so well drilled that they understand a twinkle. Most manipulations can be carried out as by an automatic apparatus, without the need of saying one word. Still, if the surgeon is very scrupulous, he would best stop performing important operations until his recovery from the ailments I have mentioned.

Easy as the maintenance of asepsis is in regard to the atmosphere and to all objects which stand boiling, so is it difficult in regard to the skin of the patient and the hands of the surgeon. Skin-bacteria are the stumbling-block in the way of perfect asepsis. The undeniable fact remains, that their total destruction or removal is practically impossible.

The surface of the human body is impregnated with many different bacterial species. Some of them adhere to the skin-surface, some are embedded in the dried cells of the epidermis. They are all accessible to sterilization. They do not necessarily need destruction, but removal. This can be done by simple me-

[1] Read at the meeting of the Medical Society of the County of New York, September 25, 1899.

[2] Fluegge: Zeitschrift für Hygiene, 1897, Bd. 25.

chanical means, viz., scrubbing with soap and water. It is made so much the easier by preliminary procedures—viz., whenever possible the patient is given a warm bath twenty-four hours before operation, the field of operation being scrubbed with green soap and shaved while the patient is in the bath. Then a poultice of ordinary green soap is applied to the skin until shortly before the operation. Thus thorough permeation of the epidermis, the dried cells of which are, in fact, macerated by this procedure, is obtained. Areas like the perineum, the scrotal and inguinal region, which are particularly rich in glands, must be scrubbed with especial care. Before the operation the skin is scrubbed energetically with linen compresses, which are dipped into hard fluid soap. This hard soap consists of green soap mixed with soft sand (Stuttgart sand). The scrubbing-process consumes about two minutes' time, and goes on while a stream of very warm water constantly flows over the surface to be sterilized. Then thin green soap is used in the same manner and for the same length of time. Particular attention is given to the folds and creases of the skin. Now the skin is dried with an aseptic towel and rubbed for one minute with a gauze compress which is saturated with fifty-per-cent. alcohol. The alcohol is not regarded as a disinfectant in the proper sense, but it is mainly used for the purpose of dissolving the fat of the skin, which is a most congenial resting-place for bacteria. By dissolving their shelter the bacteria are naturally removed.

It is self-understood that the means with which asepsis should be attained must be aseptic. This refers particularly to the water used for washing and the soap, which must have been prepared by the boiling-process. If brushes are used, special care has to be taken, as they can only with difficulty be rendered aseptic, thorough cleaning impairing their usefulness.

Whether after these procedures washing with bichloride of mercury or lysol or similar disinfectants is still needed is open to discussion. It will certainly do no harm.

There are other similar methods of rendering the surface of the skin sterile. If they are thoroughly mastered and carried out minutely they may be employed just as well. But the trouble is that underneath the skin surface a number of bacteria are sheltered by the glands of the skin, the secretions of which offer a favorable soil for their development; and these are not accessible to any disinfection or removal. Hence other means have to be chosen, to prevent their faculty of infection. And in fact they will do little harm if cared for properly.

It is evident that in incising the skin the knife dissects a number of glands and thereby exposes the bacteria contained by these glands. This undeniable fact fully explains not only the so-called suppuration of the stitch-canals, many cases of so-called late infection, and the bad reputation of the catgut, but also most of the numerous "incomprehensible" infections which develop under the supervision of the "extremely careful aseptic surgeon." Here is also the explanation of the suppuration occurring "in spite of the most minute aseptic precautions," which not only astonished many an experimenter in his laboratory, but also made him set up new surgical doctrines.

I may take this opportunity to state that bacteriological tests of aseptic methods, gained on artificial soil, cannot be applied to biological processes, the living cell reacting against bacteria differently from gelatin, agar, or serum.

That the bacteria thus set free by the skin incision find the most liberal opportunities to come into contact with the deeper regions of the wound need not be emphasized. Still, so far as my knowledge goes, there are no systematic precautions taken or advised in this direction. If a general cannot fight the enemy successfully in the open battle-field, he tries to starve him out, or he may eventually overreach or circumvent him. And the deep-skin bacteria can also be circumvented.

It seems to me that in the fierce efforts to destroy bacteria, this very simple point has been overlooked. Everywhere the old Catonic memento, "Ceterum censeo," is perceived. It may be said that the appeal in reference to bacteria, "Non ante vereri desinam, quam excisa esse sognovero," resounds from all surgical clinics. But it is invariably the "excidere" or "delere," where the searchers for improved aseptic methods get stuck fast.

Let us consider now that the dissecting-knife coming into intimate contact with these deep-skin bacteria, generally represented by the staphylococcus species, must necessarily be regarded as infected. The hands of the surgeon fall under the same considerations. This indicates two necessities: in the first place the change of the infected knife, and secondly the redisinfection of the surgeon's hands. The latter procedure may become unnecessary if gloves are worn by the surgeon while the skin is being incised.

One possibility, inoculation of the subcutaneous strata with the knife, however, remains. It cannot be obviated entirely, but can be reduced to a minimum by slowly and carefully incising the integuments alone as far as possible.

How simple it is, to set the exposed skin bacteria, which cannot be destroyed or removed, *hors de combat* by simple protection! Sterile napkins are fastened to the subcutaneous tissues with miniature forceps, such as devised by me, so that the skin-margins are so well covered by them that they do not come into view during all the subsequent manipulations, which are done then on an absolutely sterile field.

After the operation is completed the margins should be united by the subcutaneous method. If there is an absolute necessity for relaxation sutures they should be applied through the skin, but about three-quarters of an inch distant from the wound-margin, so that there is no direct contact with the wound-line. The same principle of protection should under proper modifications be employed in the opening of deep-seated abscesses. This principle was emphasized by me before in connection with the operation for pyothorax, in a paper in 1887 read before the German Medical Society of this city. Then I had tried to protect the fresh wound-margins with iodoform-ether or collodion, before I had opened the pleural cavity, in order to prevent infection from the outflowing pus. Very little attention is paid to this point, as is evident from the custom of incising abscesses, particularly appendical pus-accumulations, without regarding the incision surface at all. And what holds good for the integument applies even more to the mucous membrane. One need only consider the still existing danger of infection in intra-urethral operations. No wonder, because it is simply impossible to sterilize the urethra. It is true, sterilization of the urethra is spoken of a great deal, but practically nothing more than the desire for disinfection has been reached.

Once in a while also the so-called disposition to infection is spoken of. There is something in the theory, but only in a modified way. What favorable conditions are, for instance, offered by the skin of a working-man! And still under the most aggravating circumstances infection is but seldom found among this class in general, while among the so-called better classes the most virulent forms of infection are observed sometimes after a slight abrasion of the skin. This undeniable fact cannot be explained simply by the

difference of bacterial species or the degree of virulence. The explanation must be founded on biological grounds. The plebeian cell in the strongly developed fist of a laborer resists by virtue of its greater vitality the fiercest enemy of mankind more energetically than the aristocratic one in the little-exercised hand of a man of leisure. On the other hand there are a few members of the laboring class who show a most striking tendency for virulent infections, a fact which can be explained by the peculiar action of chemical influences. It certainly makes some difference whether bacteria are introduced into the cell in a pure state or whether they are suspended in a greasy vehicle. The cell which is able to defend itself against the naked bacterium, so to say, may be powerless against one suspended in dirty machine oil.

The principles of sterilization of the surgeon's hands are practically the same as those governing sterilization of the skin of the patient. The only essential difference is, that the surgeon's hands do not need to be incised, wherefore the deep bacteria of the skin of his hand are not exposed, provided that there are no forcible efforts made to dislodge them and squeeze them out, so to say. This would indeed be provoked only by brutal manipulations on the part of the surgeon.

I have repeatedly seen surgeons who had taken minute care in their aseptic preparations wallow around the intestine on the abdominal skin and its wound margins in the roughest manner, while manipulating it after it was taken from the abdomen for inspection. It speaks highly for the natural powers of defence of the human body, that in spite of such manipulations infection does not take place in every such instance.

So the same modus operandi holds good for the sterilization of the surgeon's hands, minus the preliminary preparations. The length of time necessary for the scrubbing of the surgeon's hands may vary according to whether the surgeon had come in contact with septic cases shortly before sterilization or whether he was positive that he had remained clean for at least the last twenty-four hours.

Furthermore the most particular care must be given to the subungual space. Wicked tongues remark of certain physicians that they carry graveyards underneath their finger nails. To clean the subungual space a Braatz's nail-cleaner is advisable. The nails must be cut short and even with scissors, not with a file. The space is then scrubbed with the rough soap first and then with the alcohol-water.

It hardly needs mentioning that the surgeon should wash himself frequently like other decent people, whether he do an operation just at the time or not. In order to protect himself as much as possible he should wear rubber gloves when coming in contact with notorious bacterial shelters like the rectum, or when examining septic cases. He should also wash with especial care after an operation.

All these principles also hold good in the question of infection in internal diseases. The clothing and body surface of a man who is surgically clean will offer a poor soil for the development of any carrier of infection. How much simple cleanliness alone can do is shown by the marvellous results of Lawson Tait.

To reduce the possibility, however, of infection communicated from deep-skin bacteria, gloves are advisable. Their use was highly recommended by me as early as in March, 1895, in my manual on "The Theory and Technique of Surgical Asepsis" (Saunders, Philadelphia), page 94. It is true that the gloves sometimes interfere with the technique of a delicate operation; sometimes, however, they permit of easier handling, as for instance in intestinal work. Cotton gloves offer no insurance against the action of bacteria, but they act as a kind of filter bag, or as a bacteria trap, in which bacteria are not killed, but arrested. When they are left off it must be remembered that the hands of the surgeon should come into contact with the wounded area as little as possible. Most manipulations can and must be done with instruments, which are always indisputably sterile after being boiled. So, for instance, a needle holder should be used while sewing, instead of taking the needle in the hand; thumb-forceps should be used for holding tissues instead of securing them with the fingers.

Erratic bacteria, which are not pressed into the wound, may perish, while in the midst of heaps of crushed cells they may develop in number and virulence. Thus may be explained why some surgeons, who perform the dreaded operation of wiring patellar fracture without touching the wound surfaces with anything but instruments, show splendid results, while the experience of others has been so sad that they have given up the operation on account of the "exceptionally great danger of infection."

These considerations bring us near another most delicate question, namely, the surgeon's manual dexterity. Since the advent of the aseptic era it seems to be supposed by many that this has become an unnecessary accomplishment. Under the auspices of asepsis countless technical sins are committed with a light animus. Some are under the impression, for instance, that if they only stick to the letter of aseptic rules they do not need to care for a minute approximation, as, for instance, of the gut after resection. But in the event of the slightest diastasis the most thorough aseptic precautions prove to be valueless in such a case, and on the other hand the invasion of a few bacteria might have done little harm, if the approximation was done with great technical skill. How else could the miraculous results of some surgeons of the pre-antiseptic times be explained? I need only refer to my distinguished teacher Bernhard von Langenbeck, the results of whose plastic operations astonished the world. And his classic rules for plastic operations were outlined long before the days of antisepsis.

Whoever saw von Langenbeck operate must have had the impression that he was an aristocrat in the best sense of the word. He had a most pronounced sense for natural cleanliness. It was not customary at his clinic to wear sterile gowns before the introduction of antiseptic rules, but the students always wondered why the master always wore a long, peculiarly made Prince Albert coat, which fitted highly over the neck, while operating. This coat was always cleaned very thoroughly, sometimes to the disappointment of the operating nurse. There was a great contrast to the non-æsthetic customs at other clinics of the same period. The hands were frequently washed and the instruments, sponges, and the ligature material were kept extremely clean. Von Langenbeck's technique was that of an artist. His work was as delicate as a watchmaker's. His anatomical knowledge enabled him to make his skin incision in conformity with the deep seat of the lesion which indicated the operation. Naturally he could also carry out his steps rapidly. Thus by the short duration of his operation he exposed his patient to a smaller risk of infection. His gentle handling of the tissues in general, his aversion against blunt operating, his predilection for sharp and clean instruments, were all points which counterbalanced to a certain degree the pre-antiseptic shortcomings. Such accomplishments should by no means be regarded as unimportant in this modern era. The surgeons should strive zealously to come as near to such perfection as possible.

Thus we can see that the success of aseptic surgery does not depend upon a few principles, but that it is

the happy combination of scientific knowledge, conscience, and manual skill, which makes the surgical master, who must thoroughly understand and regulate the thousandfold different wheels of that wonderful organic clockwork—man.

If we translate our considerations now into practice, the following maxims will result: (1) The superficial surface of the skin of the patient and of the surgeon's hands is sterilized after the principles set forth above. The atmosphere being innocuous, all inorganic material being made aseptic by boiling, the skin surface being asepticized, and the skin glands which contain bacteria being *hors de combat*, it becomes evident that the only possible source of infection remaining would be the rough manipulations on the part of the surgeon or his assistants.

(2) Aseptic gloves are worn by the operating surgeon at least during the skin incision. The assistant who passes the instruments and the one who attends to the wound itself wear gloves throughout the whole operation.

(3) After incision the wound margins of the skin are covered with sterile napkins, which are fastened to the wound surface underneath the skin margins with miniature forceps, so that the skin wound is not touched at all during the subsequent manipulations.

(4) The knife used for the skin incision must not be used for further incisions. The operation should be performed as rapidly as possible.

(5) For uniting the wound margins of the skin the subcutaneous method should be preferred.

(6) Forcible manipulations, especially blunt operating, should be avoided.

(7) The surgeon and assistants wear sterilized suits or gowns. Their heads must be covered with sterilized caps, because in bending over the field of operation it often happens that the heads of the surgeon and his assistant come in contact, whereby infectious material might be introduced into the wound.

(8) Long beards are entirely unsurgical.

(9) If a surgeon should suffer from rhinitis, tonsillitis, etc., he should use the most minute local precautions, or would better omit operating until recovery. It is self-understood that a surgeon should regard it as a crime to operate so long as he suffers even from a slight furuncle on his hand.

With the expenditure of a little more time and trouble the same principles can be carried through in private practice also.

---

## THE SURGICAL TREATMENT OF GALL STONES.

By FRANK C. FERGUSON, M.D.,

INDIANAPOLIS, IND.,

CONSULTANT IN DISEASES OF WOMEN TO THE INDIANA STATE HOSPITAL AND THE DEACONESS' HOSPITAL; FORMERLY EDITOR AND FOUNDER OF "THE INDIANA MEDICAL JOURNAL"; PROFESSOR OF OBSTETRICS, CENTRAL COLLEGE OF PHYSICIANS AND SURGEONS; MEMBER OF THE MARION COUNTY MEDICAL SOCIETY, THE INDIANA STATE MEDICAL SOCIETY, THE MITCHELL DISTRICT MEDICAL SOCIETY, AND OF THE AMERICAN MEDICAL ASSOCIATION.

THE disease known as cholelithiasis, commonly gall stones, has not heretofore received the attention from the profession that its importance deserves. It is a popular fallacy among the profession that gall stones are not of very frequent occurrence and are rarely attended with a fatal issue, and yet there are but two other surgical diseases that are of equal importance, from the standpoint of frequency of occurrence and of fatal ending when not submitted to the surgeon's knife—viz., appendicitis and ectopic pregnancy.

In looking over the transactions of our State society I find that since its organization, fifty years ago, but five papers have been read before it upon this subject. It seems to me, in view of the large mortality of this disease when treated medically, and the extremely low mortality when treated surgically, that it is high time that physicians everywhere should awaken to the necessity of surgical interference in these cases.

The liver is the largest gland in the human body, and excretes daily about three and one-half pounds of a fluid known as bile. It is situated in the right hypochondriac region, weighs from three to four pounds, and measures in its transverse diameter from ten to twelve inches, in its antero-posterior from six to seven inches. It is divided into a right and a left lobe by a fold of peritoneum, called the suspensory ligament. Proceeding from the transverse fissure are two ducts, one from the right and the other from the left lobe, which unite and pass downward to the right about one and one-half inches, where they join at an acute angle the cystic duct, forming the common duct, or the ductus communis choledochus. The gall bladder is a membranous, pear-shaped sac, about four inches in length, one inch broad in its widest part, and has a fundus, body, and neck; it is lodged in a fossa on the under surface of the liver, extending from the right extremity of the transverse fissure to the anterior free margin of the liver. The fundus is directed downward and forward to the right, and sometimes projects beyond the anterior border of the liver. The body and neck are directed upward and backward to the left. It is held in position by the peritoneum, which, in the majority of cases, passes over its under surface, but occasionally invests the gall bladder, which then is connected to the liver by a kind of mesentery. The relations of the gall bladder are as follows: The body, by its upper surface, with the first portion of the duodenum, occasionally with the pyloric end of the stomach and the hepatic flexure of the colon. The fundus is completely invested by the peritoneum, and is in relation in front with the abdominal parietes immediately below the ninth costal cartilage, behind, with the transverse arch of the colon. The neck is narrow, and curves upon itself like the italic letter *f*, and at the point of junction with the body and cystic duct it has a well-marked constriction.

I shall not weary you with dry anatomical details, but the foregoing brief description seems necessary, in order to an intelligent understanding of the surgical treatment of biliary calculi.

The gall bladder is a reservoir, merely serving to store up the bile and allow of its slow discharge into the intestine. It is difficult, says Robert Abbe,[1] to reconcile the apparent superfluousness of this fluid with its necessary storage. The horse and some other animals have no gall bladder, and seemingly it is of little or no utility in man. When it is entirely removed, his digestion and nutrition go on just as well. Furthermore, the absence of bile in the intestines, as in cases in which it escapes in its entirety by external fistulæ, is consistent with perfect health. Indeed, when reabsorbed into the system it is a distinct poison, and, according to Bouchard, it is nine times as poisonous as urine. The liver may form bile enough in eight hours to be fatal, if it is all absorbed. Physiological experiments seem to show that it is a slight but unnecessary aid to the pancreatic secretion in emulsifying fats.

Within the last few years many patients discharging all bile externally have been carefully observed by various authors, and, as a rule, there has been no difference in their daily health or bowel function unless it is an occasional tendency to flatulence. I myself have a patient upon whom I did a cholecystenterostomy ten months ago, anastomosing the gall bladder with the transverse colon, and in whom not the slightest tendency to indigestion, or to any impairment of health, has appeared. To my mind, there seems no

[1] Dennis' "System of Surgery."

reason to doubt that the bile is almost, if not wholly, an excrementitious substance, having little or no power to aid digestion, but, on the contrary, is a poisonous substance, which, if reabsorbed in moderate quantities, may be fatal in its action.

The development of biliary calculi seems to depend upon crystallization of the excess of cholesterin and bile salts, due, perhaps, to temporary stagnation and absorption of water by the walls of the gall bladder, or possibly to a transient catarrh of the mucous membrane of this organ. It is a well-known fact that the gall bladder may contain a great number of biliary calculi, and yet the possessor be totally unconscious of their presence. It is only when one attempts to pass the cystic or the common ducts that the trouble begins; a trouble, says Abbe, "that is only rivalled by labor." In many cases the calculus finally passes through the cystic and common ducts, or falls back into the gall bladder, and the patient apparently recovers. But nature is not always so successful in her efforts, for a relatively large number die while the physician is awaiting the result of nature's methods of getting rid of these bodies.

There are a number of ways by which biliary calculi may find an exit from the gall bladder. First, they may pass through the cystic and common ducts into the intestine. Second, they may, by ulceration, be discharged into the duodenum, stomach, or colon. This conservative process, however, may miscarry, and the stone be discharged into the peritoneal cavity, thus sacrificing the patient's life; or, following the direction of least resistance, or guided by natural barriers, it may, after weeks or months of torture to the unhappy victim, discharge at the navel, having followed the round ligament of the liver, or it may discharge in the loin or in the inguinal region.

The symptoms of acute hepatic colic are usually so pronounced and so uniform in character that a diagnosis is easily made. As a rule the attack is sudden. There are no prodromata. The patient is suddenly seized with an agonizing pain under the right ribs or in the region of the gall bladder, extending through the right shoulder-blade, followed by nausea, vomiting, and sweating. The pain is distinctly paroxysmal in character; it abates and returns. There is no rise of temperature, and the pulse during the intervals of the paroxysms is normal. The paroxysms of pain may cease in an hour or they may last for days. Their cessation indicates that the stone has either passed through the common duct into the intestines, or has fallen back into the gall bladder. Sometimes, however, the calculus is arrested in its progress through the common duct; it becomes impacted—neither advances nor retreats—and, the bile having no outlet, the coloring matter is absorbed, the patient becomes jaundiced, the gall bladder becomes extremely sensitive and is sometimes so distended as to be plainly felt by the hand. Here let me call attention to an important point with reference to jaundice, viz.: jaundice never appears in acute cases unless the common duct is obstructed.

The diagnosis in acute cases presents no difficulties. The paroxysmal pain, its location, nausea, vomiting, and the occurrence of jaundice within two or three days if the common duct is obstructed, the tenderness over the stomach and in the region of the gall bladder, the enlargement of that viscus when the stone has lodged in the common duct, present an ensemble of signs and symptoms found in no other disease. In chronic cases, however, the diagnosis oftentimes is attended with difficulty, and especially is this true if there is no obstruction of the common duct; for in such cases jaundice is absent, and impaction of the cystic duct may have continued so long that distinct paroxysms of pain may be absent. However, with due attention to the history of the case, the symptoms in previous attacks as well as in the present, we may usually arrive at a correct diagnosis. Chronic cases nearly always give a history of acute attacks some months or years previously, and this fact, taken in conection with the almost constant pain in the region of the gall bladder, soreness and tenderness on pressure, and, in thin subjects, the palpation of the cyst itself, all point to a correct solution. In these chronic cases the presence of impacted stones may have led to abscess of the liver or to atrophy of the cyst, and to other complications which may render the diagnosis difficult.

The prognosis in any given case of cholelithiasis, to be of any value, must be based upon the pathological conditions and the anatomical characters present in each individual case; and as it is not in the power of physician or surgeon to know, in any case, the number of stones present, their size or their exact situation, or to know the pathological condition of the gall bladder and the bile ducts, or the anatomical characters existing, it follows that a prognosis in a given case anterior to a surgical operation is a mere guess and of little value. It may be truthfully said, however, that the majority of chronic cases eventually result fatally unless surgery is called to their aid, and the majority of acute cases sooner or later become chronic.

Physicians often say that patients frequently recover under ordinary medical treatment; if by this is meant that the calculi pass through the common duct into the intestine, or, failing in this, slip back into the gall bladder, thus relieving the patient for the time being, I grant the truth of the statement. But, if it is meant that these calculi are absorbed or dissolved, or pass through the common duct, and the patient is never afterward troubled with the malady, I challenge proof of the assertion. That such a happy termination may take place in exceptional cases, I will not deny; but in medicine we must not erect exceptions into rules, unless we wish to jeopardize and oftentimes needlessly sacrifice human life. Suppose biliary calculi do frequently pass through the common duct and the patient recovers from the attack. Are you warranted in hugging the delusion that the patient is permanently well? Can you truthfully say that all calculi contained in the gall bladder have been expelled? Certainly not. Even were it possible for you to know that all the stones had passed, is it not true that, in the majority of cases, other calculi are sure to form and again place the life of the patient in jeopardy? On the other hand, if the calculi slip back into the gall bladder, is it not absolutely certain that they will go on increasing in size and sooner or later will either find their way into the stomach or intestine, or into the peritoneal cavity—most probably the latter? And this means, as you know, peritonitis and death. That biliary calculi are foreign bodies and will sooner or later escape from their imprisonment is certain. Like a stone in the bed of a stream of water holding lime in solution, they grow larger and larger by the precipitation of the constituents of the bile upon their surface, until, finally, the gall bladder is distended to its utmost limits, its walls become so thin that they give way, and the calculi, followed by bile, are precipitated into the abdominal cavity. That biliary calculi in rare cases do ulcerate their way into the stomach is true, but this does not destroy the fact that much more frequently they take the course indicated above, nor can it by any means justify the physician in withholding the only remedy that promises a cure, viz., a surgical operation.

In view of the foregoing reasons I would suggest that cholelithiasis is purely a surgical disease and should be taken out of the category of general medicine. Indeed, when we consider the anatomical rela-

tions of the gall bladder with the stomach, the duodenum, the transverse colon, and the anterior abdominal walls, together with the fact that the gall bladder oftentimes through some error of chemism becomes loaded with biliary calculi; that these calculi are, to all intents and purposes, foreign bodies and will sooner or later probably seek an outlet through one or more of the ways mentioned in the foregoing paragraph—we are forcibly impressed with the idea that the course they will take when left to nature is so uncertain that surgery is the only means by which the patient can be relieved of these dangerous bodies with but little risk to life.

If, then, we accept the doctrine, which I think the foregoing facts fully warrant, that the treatment of cholelithiasis should be surgical rather than medical, the question arises, How shall we proceed to relieve victims of this disease by surgery?

Several operations have been proposed and practised for this purpose: (1) Cholecystotomy, (2) cholecystectomy, (3) cholecystenterostomy, (4) choledochotomy, (5) cholelithotrity. Of these we shall notice the first three only.

Cholecystotomy consists in making an incision through the abdominal walls over the site of the gall bladder, opening it, extracting the calculi and suturing the edges of the gall cyst to the incision in the abdominal walls, thus establishing an external biliary fistula. This is the simplest of all operations upon the biliary passages. An incision is made vertically from the tip of the tenth rib downward three to four inches. Upon opening the peritoneal cavity the cyst will be found presenting. However, if the preceding attacks have been very severe, it may be hidden from view by adhesions, or by the colon. In this case the cyst must be carefully isolated by gently tearing apart all adhesions, and, after surrounding it with gauze or sponges to avoid soiling the peritoneum, its fluid contents are aspirated, and an incision is made through the fundus, or, what is better, a half-inch of the fundus may be cut off. The calculi are then extracted, after which the opening in the gall bladder is sutured to the parietal peritoneum and the lower part of the wound closed up to the open bladder.

Cholecystectomy, or excision of the gall bladder, may be resorted to in cancer of the cyst, when we have reason to believe that we can remove all the diseased tissue. It may also be done "when chronic atrophy has left a distorted and pocketed bladder."

Cholecystenterostomy consists in uniting the gall bladder to the intestine in such a way as to make a fistulous opening between the two, so that the bile may flow directly into the intestine. Von Winiwarter was the first to attempt this operation, stitching the gall bladder to the colon and attaching both to the abdominal wound. After adhesions had taken place he made an opening between them and sutured the opposite sides of the incision together. He finally succeeded in one case. Several years afterward Gaston, of Georgia, succeeded in uniting, in dogs, the gall bladder and duodenum. In 1889 Terrier, of Paris, succeeded in doing this operation in man. But the suture method was too difficult and dangerous to inspire many imitators. It was not until Murphy invented his button that the operation became an easy and a safe procedure, so that cholecystenterostomy is now one of the simplest and safest surgical procedures known to surgical art.

The operation of selection depends somewhat upon the pathological conditions found upon opening the abdomen. Should the gall bladder be found so extensively diseased or so greatly atrophied that its attachment to the colon or the duodenum is impracticable, cholecystotomy or cholecystectomy may be done. One such case has occurred in my practice, which will be reported below. In all other cases cholecystenterostomy is, in my judgment, the ideal operation: first, because drainage is made into the intestinal canal instead of externally; second, convalescence is much more rapid; third, the patient is permanently cured.

In the treatment of cholelithiasis, as in all other curable diseases, we should select that remedy which promises a speedy and a safe cure. Mere palliative remedies, whether they be medical or surgical, are pernicious, mere makeshifts, and often lead to a fatal issue. In laying down the proposition that cholelithiasis is a purely surgical disease, I am in accord with the best modern authorities. However, do not understand me as saying that we should resort to an immediate operation in every case. In first attacks of hepatic colic tentative treatment is allowable. The attack may pass away in a few days and the patient apparently recover. But he should be warned that sooner or later the attack will in all probability recur, and a surgical operation may be necessary to save his life. But in acute attacks attended with jaundice and lasting longer than from ten days to two weeks, and in which there are no signs of improvement, operation is indicated. In all acute cases, unattended with jaundice, lasting for a week or more without improvement, operation is unmistakably indicated.

In all chronic cases, namely, cases in which there has been a recurrence from time to time of hepatic colic, whether there is or is not a coincident jaundice, operation is indicated. Then there is another class of cases, chronic in nature, that drag their slow length along for months, sometimes for years, in which the distinctive symptoms of gall stones have been merged into constipation, chronic indigestion, anæmia, soreness, and sometimes excessive tenderness in the epigastric region. Jaundice, if present at all, is very slight. Such cases are frequently treated for malaria, "bilious fever," or "liver disease." The gall bladder in such cases is liable to undergo cancerous degeneration and should be operated upon without delay.

In conclusion, I beg leave to report, in illustration, a few cases that have come under my care within the last year.

Mrs. S——, aged thirty years, married, the mother of three children, consulted me in August, 1898. She had suffered for six years, at intervals varying from two to six weeks, with paroxysmal pain, having all the distinctive characteristics of hepatic colic. She was now four and a half months pregnant. Since the beginning of this pregnancy the intervals between the attacks of colic had grown shorter until, when I saw her, she was having three or four attacks a week. She was markedly jaundiced and her stools were clay-colored. A diagnosis of impacted gall stones was made, and an operation was recommended. The woman was removed to the Deaconess' Hospital, and, after proper preparatory treatment, I performed a cholecystenterostomy, removing thirty-two gall stones, two of them the size of a small marble, the remainder not so large. The gall bladder was attached to the transverse colon with a Murphy button. Recovery was rapid and without a single bad symptom. The hepatic colic ceased immediately after the operation, and in January last the woman was delivered at full term of a living child. Up to this time she has remained perfectly well.

Mrs. T——, aged forty years, married, has given birth to two children. The family history is good. I was called to Danville, Ind., to see her in consultation with her physician, about one year ago. She had been confined to her bed for eight weeks, and was being treated by her physician for "bilious fever." The past history and present symptoms pointed unerringly to impacted gall stones. To this diagnosis her physician demurred, and, although I begged permission to

operate, the family physician's influence with the husband exceeded my own, and operation was refused. The woman died some two weeks after my first visit. I succeeded in getting a post-mortem examination, which was made by Dr. T. B. Noble, in the presence of Drs. Barker, Farabee, Lawson, and two or three other physicians of Danville. The cyst and its duct were found impacted with five large gall stones, which had caused her death.

Mrs. W——, aged forty-five years, mother of several children, had been suffering from attacks of pain in the region of the back and gall bladder for twenty years. I saw her in consultation with Dr. Noble about April 12, 1899. Dr. Noble had made a diagnosis of gall stones, in which I concurred. She had been confined to her bed for about two months, suffering intense paroxysmal pain, having all the characteristics of hepatic colic, and accompanied with jaundice, clay-colored stools, etc. She was greatly emaciated, anæmic, and profoundly prostrated. She was removed to the Deaconess' Hospital and prepared for operation. On April 17th, assisted by Drs. T. B. Noble, Martha J. Smith, W. B. Ryan, and Dr. Christian, of Glen Valley, Ind., I removed two hundred and three gall stones, ranging in size from a grain of wheat to that of a small almond. The cyst was united to the transverse colon by a Murphy button and the abdomen was closed. The patient rapidly convalesced and returned to her home on the twenty-third day after the operation, feeling perfectly well, although the button had not yet made its appearance. In this case the walls of the gall bladder were greatly thickened, and this accounts for the long delay in the appearance of the button, which was passed ten weeks after the operation.

Mrs. T——, aged thirty years, married, had given birth to four children. She was always healthy and strong until three years ago, when she had a violent attack of paroxysmal pain, followed by vomiting. These paroxysms recurred frequently and at shorter intervals until she became a confirmed invalid and a morphine habituée. Notwithstanding the fact that jaundice and clay-colored stools sometimes followed these attacks, a diagnosis of gall stones had never been made by the physicians who attended her, until April 13, 1899. At that date she consulted Dr. T. B. Noble, who made the diagnosis, and asked me to see her, with the view of an operation. On Tuesday, April 16th, she was admitted to the Deaconess' Hospital and put upon preparatory treatment. On Thursday afternoon following she had a terrific attack of hepatic colic, requiring morphine in heroic doses every hour or two, with whiskey, and occasionally inhalations of chloroform, to make the pain bearable. From Thursday until Friday morning she had received gr. xv. of morphine hypodermically, and yet she was in great agony. The operation was performed at nine o'clock Friday morning. When the abdomen was opened the gall bladder was found greatly atrophied, and containing one gall stone, the size and shape of a cherry, in the fundus. The fundus was found adherent to the pyloric extremity of the stomach, showing that nature was trying to eliminate the stone in this way. After separating the adhesions I found it impossible, on account of the atrophied state of the cyst, to anastomose it with the intestine, or to lift it up sufficiently to attach it to the severed edges of the peritoneum. While considering the propriety of exsection Dr. Noble suggested the stripping of the peritoneum from the abdominal walls, bending it down, and suturing it around the atrophied fundus. This suggestion was immediately acted upon. The cyst was opened and the stone extracted, and the lower part of the abdominal wound was then closed, the bile being allowed to escape externally. The patient made an uninterrupted recovery. For the first four or five days the bile escaped so profusely as to require several changes of dressing daily. It then gradually diminished in quantity, until, at the end of a month, the abdominal wound had completely healed, and the patient was discharged.

Mrs. B——, aged forty-eight years, married, had given birth to several children. Dr. Ryan was called to her first on the day before her death, November 15, 1898. She was suffering from great pain in the region of the stomach, accompanied by nausea and occasional vomiting. Dr. Ryan made a diagnosis of gall stones and gave palliative treatment, assuring her that nothing but a surgical operation would prove curative. The following evening the doctor asked me to see her. When we arrived, having been delayed several hours, she had just expired. No well-defined history of the case could be had from the relatives, but the gall bladder, which was removed at the post-mortem examination by Dr. T. B. Noble, tells its own story. It tells us of repeated attacks of violent hepatic colic in past years. It tells us that these gall stones, two of them as large as buckeyes, had made repeated trials and failures to escape from their imprisonment through the cystic duct. An opening just over the largest stone tells us that in her last and fatal attack the organ ruptured, bile was precipitated into the peritoneal cavity, and septic peritonitis supervened. In its mute eloquence it tells us of the conservative powers of nature; how, in her beneficence, she enlarged its cavity, extended its length, increased the thickness of its walls, so as to make room for the increasing size of the stones and raise a barrier against their escape into the peritoneal cavity. This specimen also tells us that the life of the woman could have been saved by a skilful surgical operation at any time previous to the last attack.

But I have not the time to dwell further upon these interesting cases, some of them so tragic in their ending. They carry with them their own lessons—lessons which, if learned and remembered, will result in the saving of many valuable lives.

19 West Ohio Street.

## A NEW METHOD OF REDUCING OLD DISLOCATIONS OF THE LOWER JAW.

By THEODORE A. McGRAW, M.D.,

PROFESSOR OF SURGERY IN THE DETROIT COLLEGE OF MEDICINE.

Having failed to reduce an ancient dislocation of the lower jaw by the usual methods, I was forced to invent a procedure which is so simple and yet so effective that it seems to me worthy of record.

James Loder, aged thirty-two years, while walking in his garden on the morning of June 6, 1898, suddenly fell paralyzed in his left arm and leg. The history of the case is not clear, and it is uncertain whether his jaw was dislocated when he fell or immediately afterward while yawning. However that may be, the symptoms of dislocation made themselves manifest immediately after the fall and continued without intermission until I reduced it. There was a gradual but nearly complete recovery from the paralysis of the leg and thigh, and to-day they seem as sound and powerful as their fellows. The left hand and arm, however, still show the effects of the stroke. The hand especially is shrunken and stiffened. Its muscles are atrophied and its motion is much impaired. The evident paralysis apparently blinded the man's many physicians to the true nature of the deformity and loss of function of the jaw.

His difficulty of speech was referred to a paralysis of the muscles of the mouth, and the inability to close his mouth to spasm and permanent contraction of the

depressor muscles of the chin. It was not until October, when he fell into the hands of Dr. David Inglis, that a correct diagnosis was made of his injury. About the middle of October Dr. F. W. Robbins made a prolonged but unsuccessful effort to effect the reduction of the dislocation with the patient under anæsthesia.

I saw him for the first time on November 2d in my clinic at St. Mary's Hospital. I found a man of magnificent proportions and great muscular development, with typical symptoms of a bilateral dislocation of the lower jaw. There were marked hollows in front of both ears. The jaw was open and thrust forward so that the chin protruded. The motion of the jaw was extremely limited. The teeth could not be brought together; mastication was impossible, and the speech was much impaired. During the five months which had elapsed since the injury, no improvement had taken place in the motion of the jaw. I was unable to discover the cause of the paralysis. He had not been ill before, and the suspicions entertained of syphilis were not confirmed by his history or by any existing symptoms. His heart sounds were clear and his urine was normal. It is possible that he may have suffered from some form of embolism. The man was put under chloroform, and I made a protracted effort to put the jaw in place by traction, by inserting wedges between the teeth, by Nélaton's method, and in fact by all methods which could be used without especial apparatus. I failed completely, and could not see at the close of the trial that the condyles had been stirred in the slightest degree from their abnormal position.

On November 9th I made a new attempt on a different plan. I provided myself with a strong steel hook; it was made especially for the purpose, with a short prong bent in such a way as to run parallel to and near to the shaft. The space between the prong of the hook and its shaft was just wide enough to permit the hook to pass over and grasp the jaw at the sigmoid fossa. I purposed making incisions under each zygoma, separating the fibres of the masseter, passing the hook through in front of the condyle on each side and over the bone at the sigmoid notch, and then pulling downward and backward until the condyle was disengaged and slipped into place. In carrying out this plan, I made first a T-shaped incision below the right zygomatic arch. I found it easy then to pass the hook through the masseter by separating but not dividing its fibres, and to fasten it over the bone in front of the condyle. Pieces of cork were inserted between the molars as far back as possible, and an assistant was directed to pull the chin forward and upward with all of his force, while I myself made traction on the hook. This was continued over fifteen minutes before I could feel the jaw yield to the strain. It was rendered more movable, but could not as yet be replaced in its normal position. I now made a straight and short cut under the left zygoma and succeeded in passing the hook as before. Repeating on the left side the efforts I had made before on the right, I had soon the satisfaction of feeling the bone slip into place. The chin fell back to its proper position; the teeth were brought together, and motion was restored. The jaw was kept bandaged for two weeks, and all motion forbidden. The patient took nourishment in fluid form without opening the mouth. It was interesting to note how after a few days the jaw seemed to settle more and more into its normal relations. Directly after the operation there remained a slight projection of the teeth and an abnormal fulness over the joints. This gradually disappeared, and the man left the hospital with the form and function of the jaw perfectly restored. The operation was followed by some inflammation and suppuration, which, however, soon subsided, and his recovery was perfect. I found on trial that the first incisions, those made on the right side, were unnecessarily long, and when I operated on the left side I contented myself with a straight cut about an inch in length. I am satisfied, however, that this, too, was longer than necessary, and in another case I should content myself with the very smallest incision which would permit the hook to pass through the muscle and over the jaw. The fibres of the muscle are easily separated, and the hook can be passed over the sigmoid notch without exposing the bone to view. On traction the muscle would yield and the elasticity of the skin would make no opposition to the downward pull. Although I have found, in several systematic works on surgery, the advice to proceed, in case of failure to reduce the dislocations of the jaw to operative measures, it is curious that no such author whom I have been able to consult has described any such operation or cited any cases. The only cases of operations made for this purpose which I have been able to find in the periodical literature were:

(1) That of Brockway.[1] A bilateral dislocation of thirteen months' standing in a woman thirty years of age, after unsuccessful trial of other methods, was reduced by making incisions below the zygomas, exposing the condyles and the glenoid fossæ, and prying the condyles out of their abnormal positions by some blunt instrument. The use of the jaw was fully recovered.

(2) Two cases of Dr. R. H. M. Dawbarn.[2] Dr. Dawbarn presented a patient who had suffered a long time with an unreduced bilateral dislocation of the lower jaw. Several unavailing attempts had been made to reduce it. Dr. Dawbarn had made incisions almost dividing both masseter muscles, enabling him to reach the displaced bone and pry it back into place. The result was permanent and satisfactory. In another case the speaker had been able to effect reduction after nearly dividing only one of the masseter muscles.

(3) Mazzoni, of Rome,[3] has described an operation for the relief of an irreducible dislocation of the lower jaw of eight days' duration. He resected both condyles, and after three months' treatment had a successful result.

Old dislocations of the lower jaw are not common. The inconvenience arising from the injury makes the patient generally clamorous for aid, and the symptoms are so pronounced that mistakes in diagnosis rarely occur. The reduction of the recent luxation is usually not difficult, and cases of this kind are rarely neglected so long that the bone becomes fixed in its abnormal position. As regards the instrumental methods in vogue for the reduction of difficult dislocations of the jaw, they are all based upon the use of force exercised within the mouth by means of wedges and levers. The fulcrums for this leverage are the molar teeth, upon which the instruments rest and which are pried apart. But force applied within the mouth is exerted at great disadvantage. In an old dislocation, a pressure applied to the molar teeth sufficient to break adhesions, stretch the contracted temporal muscles, and disengage the jaw must endanger the teeth. How many such teeth have been broken in attempts at reduction does not appear in the records. Probably the surgeons have thought the matter too trivial for mention, and yet it is no small matter to suffer the loss of molar teeth. However that may be, there will be occasional cases which will resist all such efforts at reduction. For such, the surgeon has a choice of two operative procedures, the one that adopted by Drs. Brockway and Dawbarn, of incisions over the glenoid cavity and through the masseters, the exposure of the

[3] Gazeta Medica di Roma, 1877, No. 4.

injured bones, and then reduction by prying the condyles out of their false position by means of chisels or similar instruments. In so doing the fulcrum of the lever must be the zygoma itself. The other method is that which I have just described. When it is taken into consideration that by the use of a hook and traction it is not necessary to expose the bone or joint, or to cut the masseter across its fibres, I do not think that there can be any question that my method is the simpler and better. In the one case which I have reported, I made incisions unnecessarily long. I know now that the operation could be done through a cut so small that it would be practically subcutaneous.

For the investigation of the literature of this subject, I wish to express my obligations to the National Bureau of Medical Bibliography in Washington.

## SUPPLEMENTARY NOTE ON THE ETIOLOGY OF SCARLATINA.

By W. J. CLASS, M.D.,

CHICAGO, ILL.

THERE are a few further features of importance in regard to the diplococcus of scarlatina which have been omitted in the writer's previous reports on this subject. That the causative factor of scarlet fever is a diplococcus there can be but little doubt; diplococci have been found in the blood of scarlet-fever patients not by the writer alone, but by a number of other competent observers. The morphology of these diplococci has differed somewhat, to judge from the descriptions published. A further item indicating that a diplococcus is in all probability the cause of scarlatina has come to the writer's notice since the publication of his last report. Dr. Grünbaum,[1] at a meeting of the Liverpool Medical Institution, mentioned the fact that in experimenting with the agglutination test

FIG. 1. Large Cocci grown on Earth Agar, old culture. × 1,000.

he had made the discovery that a certain diplococcus taken from a scarlet-fever patient was agglutinated by the serum from another scarlet-fever patient; he did not, however, give any further description of the organism. The variance in the morphology of the diplococci found in the blood of scarlet-fever patients by different observers corresponds with the experience of the writer in his work on the germ described in the MEDICAL RECORD of September 2d. This germ varies greatly in size and shape, and although the form usually seen in primary cultures grown on the earth agar is the diplococcus resembling a very large gonococcus, still the primary culture may show it in one of its other forms. In order to prove the identity of the organisms it becomes necessary to make successive transplantations of the culture from one culture tube to another; allowing it to grow for a few days at the least before

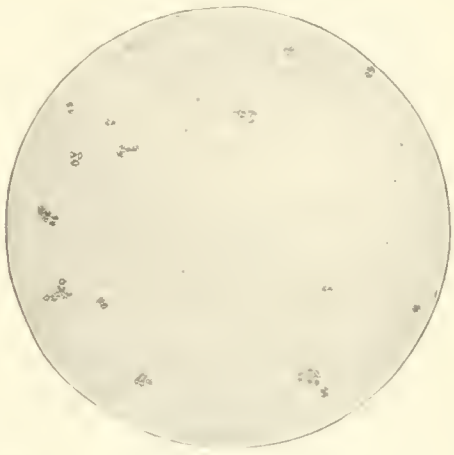

FIG. 2.—Usual Form as Seen in Throat and Scale Cultures. × 1,000

transferring to a fresh tube. The different forms can be best studied by beginning with a culture of the large diplococcus; by transferring a loop of this culture to another tube of earth agar, and allowing it to

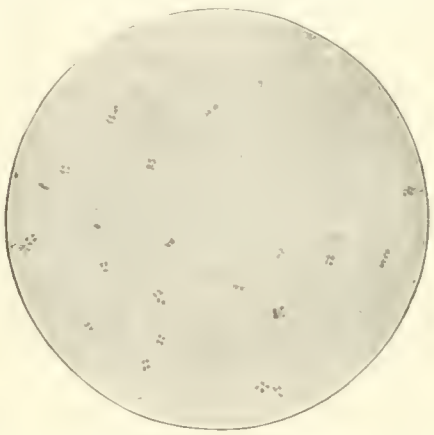

FIG. 3. Involution Forms, Tetrads, and Long Coccus resembling a bacillus, formed by the longitudinal division of the diplococcus. × 1,000.

grow for a few days and then making an examination of the growth, it will be found to consist largely of tetrads; by the still further division of the tetrads in the next subculture, small diplococci are formed, and,

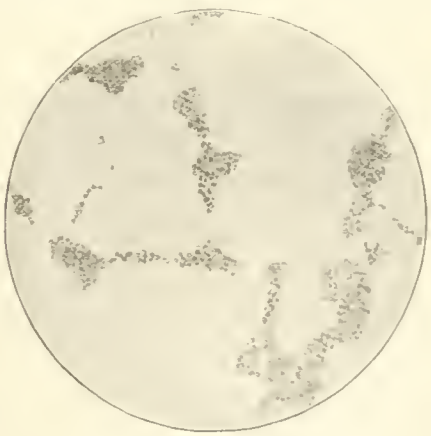

FIG. 4.—Small Cocci in Bunches, Showing Pseudo-Capsule. × 1,000

through the division of these, single cocci, etc. As Page' has pointed out, other organisms in the primary

cultures frequently grow through the glutinous substance holding these cocci together, the two being intimately mixed; this may give rise to very misleading pictures. It is probably this condition in which extraneous bacilli have grown into the glutinous substance which Klebs has described as "monas scarlatinosum." The accompanying reproductions of micro-photographs represent the forms of this organism most generally encountered.

## THE PULSATORY HAND AND FOOT PHENOMENA.

By W. MOSER, M.D.,

BROOKLYN, N. Y.

In placing the palmar (inner) surface of the two hands together, as in the attitude of prayer, and making slight pressure with each finger tip, a visible pulsation, capillary in origin, is not only felt, but seen in most individuals. If too much pressure be made with the finger tips it is not visible, since we know that by compression of a vessel we may shut off the circulation. This finger or hand pulsatory phenomenon, like the foot phenomenon, which occurs when the legs are crossed, possesses some practical or diagnostic significance, and notably is that the case in aortic regurgitation, in which sphygmographic tracings will show a much higher ascent than normal, the condition in question being a demonstration of "Quincke's capillary pulse." By studying a number of normal cases first, and then abnormal, this sign will prove of diagnostic and probably prognostic value. I look upon both these pulsatory phenomena as principally capillary in origin. But the central point is the heart, and disease of this organ, as aortic regurgitation or a rapid and forcible heart, will increase or render more visible these pulsatory phenomena. It is a good index of the central station, and may prove of especial service to those who are not well acquainted with the auscultatory phenomenon.

## ANOMALY OF THE LONG TENDON OF THE BICEPS MUSCLE OF THE ARM.

By JOSEPH D. CRAIG, A.M., M.D.,

ADJUNCT PROFESSOR OF ANATOMY, ALBANY MEDICAL COLLEGE.

The following anomaly of the long tendon of the biceps muscle of the arm is believed to be of sufficient interest to warrant its being made a matter of record. The anomaly was found in a dissecting-room subject in the Albany Medical College, and in the left shoulder-joint of a man evidently a laborer, about middle life and of strong muscular development. The shoulder-joint on the right side was normal in all respects, the long tendon of the biceps passing through it in the usual way, surrounded by the usual synovial sheath and supported in front by the thickening of the capsule which is sometimes called the gleno-humeral ligament (Flood's). The anomaly was on the left side alone. On this side the long tendon of the biceps of the arm was not found within the shoulder-joint in any part of its length. The transverse ligament usually found between the tuberosities of the humerus was much thickened and was intimately blended with the insertion of the biceps tendon immediately behind. This ligament was also prolonged downward, was much thickened, and laterally was attached to the margins of the bicipital groove, gradually blending below with the deep fascia. The long tendon of the biceps, starting below at the belly of the muscle, proceeded upward along the bicipital groove, but instead of being free within it, as is usual, and surrounded by a synovial sheath, had little or no investing synovial membrane, and gave off strong lateral fasciculi which became gradually blended with the transverse ligament and were finally attached to the margins of the bicipital groove. So the tendon proceeded until it reached the interval between the bicipital tuberosities, where it stopped abruptly, becoming intimately attached to the bottom of the groove and all the surrounding structures. There was no part of the tendon within the joint. Neither was there any trace of Flood's ligament. The supra-glenoid tubercle was only a small nodule. In other respects the arrangement of the structures about the joint was normal. There were no evidences of pathological change in the joint, no thickening of the ligaments, no roughening of the synovial surfaces. The arrangement must have been congenital. Complete absence of the tendon of the biceps from within the shoulder-joint must be very rare, and for this reason this case seems to be worthy of record.

---

## A TACK IN THE LUNG FOR SEVEN YEARS.

By ANDREW V. JOVA, M.D.,

NEWBURG, N. Y.

A young man, seventeen years old, a driver by occupation, complained of having had a severe cough with expectoration for seven years. On April 24th, he complained that the cough had been worse for three weeks; he was unable to eat, and felt very weak. He had had a slight hemorrhage a few days before. The tongue was thickly coated. Expectoration was profuse and very fetid. Respiration, 44; temperature, 104° F.; pulse, 146. April 25th physical examination of the chest showed, on the left side, percussion normal; there was exaggerated respiratory murmur over the entire lung with slight roughness. On the right side percussion was normal in the upper part. The respiratory murmur was slightly bronchial, and there were a few moist râles. In the lower part, especially over the back and side, percussion was dull, and there was almost complete absence of the respiratory murmur. The symptoms continued about the same on April 26th and 27th. During the night of April 27th–28th the patient coughed up a hard substance surrounded by thick mucus of a dark color. On examination this proved to be a tack seven-eighths of an inch in length, well preserved except that it was covered with rust. On the following morning the respiration was 30; pulse, 100, and temperature, 102° F. There were abundant moist râles over the upper part of the affected lung. Over the lower part, besides large moist râles, there was a gurgling sound, and over a circumscribed space about two inches in diameter cavernous breathing. Three days later the respiration, pulse, and temperature were normal. To-day (May 14th) the patient is practically well and able to resume his occupation, but he still coughs a little, and there is some dulness over the lower part of the lung with broncho-vesicular breathing. The mother of the young man informs me that seven years ago, when he was ten years old, he had swallowed a tack while playing. He had experienced a slight choking sensation at the time, but it soon passed away. He had coughed ever since, however, and she consulted several physicians, who ridiculed the idea of the tack and told her the boy had bronchitis.

## EMPYEMA, SACCULATED BETWEEN THE HEART AND THE LUNG.

By WILLIAM S. DODD, M.D.,
CESAREA, TURKEY IN ASIA.

The following case of empyema may have interest for others as well as myself, because of the failure to locate a circumscribed abscess in the chest:

Mr. H——, an American, aged fifty-seven years, was a man of muscular build, strong constitution, and, as he said, had hitherto never known a day's sickness. About Christmas time he had a carbuncle on the back of his neck, and this was followed by boils. He continued very hard at work, taking no time for rest and recuperation. On February 20th he was taken sick with pneumonia involving the lower lobe of the left lung. On March 4th his temperature had returned to normal, but the next day it rose to 101° F., and continued thereafter with morning and evening fluctuations varying from 99.5° to 103.5° F.

I saw him first on March 31st. On examination, the left side of the chest did not appear enlarged nor were the intercostal spaces bulging. Percussion in front gave dulness from the third rib downward, and from the edge of the sternum to the mammary line. Auscultation corresponded with this, giving vesicular breathing over the resonant portions. Behind there was dulness from the seventh rib downward, respiration not being heard below that line, and above being vesicular in character though diminished in intensity. Puncture in the seventh space gave pus.

An operation was performed the next morning. Two inches of the eighth rib in the mid-axillary line was resected and the pus evacuated. The amount was small, about 250 gm. by estimation, but there were considerable masses of consolidated fibrin, one of which, half the size of my hand, came away with the irrigation two or three days later.

The temperature fell to normal that evening, but was worse again the next day. The cough became more violent and paroxysmal, and the sputum purulent in character, which it had not been before. Morning and evening irrigations with plain boiled water were employed. The course of the fever, differing but little from that before the operation, convinced me that there was another abscess, and the most careful search was made to discover its locality. Posteriorly the lung had expanded, vesicular breathing being heard to the base of the lung, though it was naturally faint. Anteriorly, the only change to be found was that the apex beat, which previous to the operation had been nearer to the sternum, had returned to within half an inch of its normal position. I have neglected to say that the patient had complained of a spot of considerable tenderness at the junction of the fifth rib with the sternum. The area of tenderness was no larger than the end of my finger. No trace of fluctuation or œdema could be discovered. This tenderness dated from some time previous, probably as early as the first part of March. At first there had been a slight swelling there, but that had passed away.

The further course of the disease it is unnecessary to follow. Death took place twelve days after the operation, the final cause being an embolism in the left side of the brain.

At the autopsy the finding was as follows: The right lung was normal; the left lung was fully expanded and filling the entire pleural cavity, adherent over the whole surface, anterior and posterior, except where the drainage tubes were, and that cavity was quite small. The adhesions were thick and firm on the anterior surface and on a part of the diaphragm, yielding only to dissection. An encapsulated abscess was found between the pericardium and lung containing perhaps 300 gm. of pus. This was covered in by the lung, and was in relation to the anterior wall of the chest only in the fourth intercostal space from the mammary line for about 3 cm. toward the sternum, but the pericardium was directly under a part of this. A needle in the fourth intercostal space 1 cm. internal to the mammary line would probably have found the abscess without entering the pericardium and carrying infection with it. At the end of the fifth rib, corresponding to the point of tenderness described above, the bone tissue was found broken down and necrotic. A small bit, as large as the head of a pin, of what may have been inspissated pus, was found in one of the deeper cells. Although the abscess extended in the direction of this spot, no communication could be found; neither could any communication be found between the abscess and even the smallest bronchi. The walls of the abscess were thick and tough. The lung tissue was dark red, congested, and œdematous. The other findings it is unnecessary to describe.

The question that concerns me is this: In view of my conviction that there was another abscess, and finding no other area of dulness than that corresponding to the heart, ought I to have ventured to put the exploring needle into the outer edge of this area?

## A SEVERE CASE OF ECLAMPSIA COMPLICATED BY A MARKED ERYTHEMA MULTIFORME.

By JAMES D. VOORHEES, A.M., M.D.,
NEW YORK,
INSTRUCTOR OF OBSTETRICS AT THE COLLEGE OF PHYSICIANS AND SURGEONS, RESIDENT PHYSICIAN AT THE SLOANE MATERNITY HOSPITAL.

L. B——, aged twenty-one years, was admitted to the Sloane Maternity Hospital February 12, 1899, with the following history: The patient had had scarlet fever when seven years old. During her pregnancy she suffered from considerable nausea but no vomiting. At times she had slight headaches. For three weeks before admission she had noticed a slight swelling of the ankles. There had been no trouble with her eyesight, and she had passed plenty of urine. After breakfast, February 12th, she complained of backache, and while sitting in a chair, without any warning whatsoever, had a severe convulsion, followed by coma. She had three other convulsions during the morning, and then was brought to the hospital by an ambulance.

On admission, 1 P.M., the patient was unconscious. The breathing was stertorous, and the pulse slow with considerable tension. There was no œdema. Nine ounces of urine were obtained by catheter. It was clear and pale; reaction acid; specific gravity 1.010. It contained only two per cent. of albumin on boiling, and there were a moderate number of blood and epithelial casts. The patient was at her eighth month; child lying L.S.A.; the cervix was long and tough, but both the internal and external os admitted one finger. She was immediately started on light chloroform anæsthesia and given Magendie's solution ℥ss. hypodermatically. The indication was to deliver. This was accomplished with some difficulty on account of the rigidity of the cervix and its immaturity. It was first manually dilated as far as possible, then more so by pulling down a foot. It began to tear on the right side. To prevent this tear from extending up into the lower uterine segment Dührssen's incisions were made anteriorly, posteriorly, and on the left side. The breech then came through and was born, but the after-coming head was gripped in the cervix. It was easily delivered with the forceps. A living child was born at 4:54 P.M. It weighed four pounds nine ounces. The mother stood the delivery

very well and was in good condition just after the operation.

At 6:10 P.M., the patient was slightly conscious and took calomel gr. v. by mouth. She was also given chloral gr. xx. by rectum and started on nitroglycerin gr. $\frac{1}{100}$ every hour hypodermatically. Everything seemed to be progressing nicely and the prognosis given was good. Notwithstanding, at 7:04 P.M. she had a very severe convulsion. Magendie ℥vi. was then given, and more chloroform.

At 9:35 P.M., after being in a hot pack for half an hour, the patient had another seizure in which she almost died. Her color became very cyanotic and the pulse was imperceptible for a few minutes. After this during the night her condition was very poor. Two other seizures were aborted by the use of chloroform, and the morphine was pushed to a point where the respirations were lowered to twelve a minute. These two drugs, however, seemed to do harm. The patient's breathing became labored as well as slow, followed by some cyanosis, and in the morning some œdema of the lungs had commenced. The pulse increased to 128 without tension; so both were discontinued as well as the nitroglycerin, and instead a few doses of digitalis were substituted. At 9 A.M. a continuous rectal irrigation of hot decinormal salt solution at 116° F. was started and continued for an hour. She was passing plenty of urine. Seven and a half ounces were obtained at 9 A.M. by catheter. This showed only a trace of albumin. At 10 A.M. her improvement was very manifest. Her color and breathing were much better; the pulse was slower and stronger. By noon she was conscious. After this she was practically well. Some headache bothered her for about twelve hours. Her urine was excreted in large quantities, and the analysis was negative as early as the second day. One peculiar symptom was a moderate jaundice which lasted a few days. As far as her eclampsia was concerned she was well in thirty-six hours after delivery.

On the morning of the seventh day, February 18th, a bullous eruption was discovered involving most of the extremities and the body. This had come out during the night without any premonitory symptoms, and the rapidity with which it spread was marvellous. The serous patches varied in size from that of a pea to almost that of a goose egg. Some of them were isolated, but most of them were crowded closely together. Individuals and groups were surrounded by erythematous areas. The bullæ were elevated and of different shapes—rounded, ovoid, and irregular in outline. The epidermis was very thin over them, and the contents were clear, yellowish serum. The eruption itched somewhat, but not intensely. At the onset there was no elevated temperature.

On the next day the face became involved and the hands more completely. About the nose and mouth numerous small vesicles appeared. On the fingers and toes, palms, and soles the bullæ were very large and irregular. Some of them were at least 6 to 7 cm. in diameter and contained an ounce or more of serum. One finger was surrounded by one tense bulla from almost the tip to the hand. At the navel also there was one immense one almost the size of a fist.

In the axillæ, cubital fossæ, in the groins and popliteal spaces, the bullæ and vesicles were very confluent, and when they had broken produced very marked irritation.

On February 20th the mucous membrane of the mouth was affected; the roof of the mouth, the gums, and tongue being involved. These vesicles soon ruptured and produced little ulcers, rendering talking and swallowing painful.

By February 22d—the fourth day of the eruption—it was at its height. About nine-tenths of the body was involved. The scalp now was covered with numerous large and small vesicles. The temperature and pulse began to rise, the former to 102° F. and the latter 124 in the afternoon. After the bullæ ruptured excoriations were left. Some of these were covered with a scab and in dry places soon desiccated and desquamated. Others, especially in the moist places, like the axillæ, elbows, groins, popliteal spaces, and ankles, became superficial ulcers with an excessive thin, acrid, serous discharge. These, when scratched, bled easily, and some of them were infected. Very few bullæ or vesicles suppurated. Many of the ulcers were surrounded by reddened and inflamed areas. Only one gland was enlarged. That one was of the upper posterior cervical group which drained the scalp. From February 22d to March 4th the patient ran a temperature between 99.6° and 102.4° F., probably due to a mild sepsis.

During the time there were successive relapses in the eruption. In the new skin new bullæ and new vesicles formed, and in some localities there were as many as four different crops. In each relapse, however, the bullæ were smaller and covered less and less extensive areas.

By March 9th—the nineteenth day of the eruption—the face and the body were clear; there was still some desquamation of the hands and feet, but there remained only a few small ulcers, the size of a dime, on the ankles.

On March 20th the patient was discharged perfectly well, and all that remained of the eruption were a few cicatrices about the ankles. The treatment of the case consisted in milk diet, cathartics, salicylate of sodium for one week, and then sodium iodide internally. Externally at first for the moist stage an ointment of zinc oxide, starch, and salicylic acid was used; during the dry stage a powder of stearate of zinc. Sedatives were given for the itching and chlorate of potash for a mouth wash. There are many points of interest in this case:

(1) It was one of those cases of eclampsia in which the urine was excreted in large quantities, in which the specific gravity was low and there was little albumin. Such cases are very uncommon in our experience at the Sloane Maternity Hospital. This fact shows that the condition is a toxæmia when other organs than the kidneys are at fault. This woman was afterward jaundiced. This points to the liver. Therefore we assume that the liver must have produced the toxins, or it failed to excrete the toxins, or it must have been affected by the toxins which caused the convulsion. In the light of post-mortem findings this lesion is a hemorrhagic hepatitis.

(2) The case also indicates that if a woman has had but one eclamptic seizure we must always give a guarded prognosis. Even if the uterus is empty, even if the kidneys are active, even if the pulse is slow and there is no pyrexia, even if the coma is transient, the outcome is not always a recovery.

(3) Again we learn that morphine, chloroform, and hot packs must be given with care and judgment. Convulsions will occur even when these drugs are given in fairly large doses, and then there is the danger of a cardiac depression manifested by œdema of the lungs. Any slight indication of such an unfavorable turn requires an immediate cessation of such remedies. In these cases, in our later experience, while there is tension to the pulse, veratrum viride has acted with very good results.

(4) The skin lesion—erythema multiforme in a bullous form—even of itself is very rare, and I cannot find a record of such a case during the puerperium. At the Sloane Maternity Hospital and in the various journals there are cases of simple and papular erythemata reported, but none in which bullæ were developed.

As to the etiology of the eruption, perhaps the liver in its resolution elaborated a toxin which affected the skin. Kaposi puts the causes of this skin disease under four headings: Case due to (*a*) change of seasons; (*b*) angio-neuroses which occur principally in women; (*c*) instability of the vasomotor centres: (*d*) auto-infection, *i.e.*, toxic substances which have entered the blood as the result of some internal disease as chronic nephritis. Our case probably comes under the last division.

Some other unusual points about the erythema were the rapid onset without any prodromal constitutional symptoms, the rapidity of the primary general involvement, and the number of relapses.

That the patient escaped a general septicæmia was very gratifying.

This case occurred during the service of Dr. E. B. Cragin, with whose kind permission I publish it.

447 West Fifty-ninth Street.

## EXCISION OF THE HIP: WITH SKIAGRAPH TAKEN AFTER FIVE YEARS.

By A. E. ISAACS, M.D.,

NEW YORK,

ASSOCIATE PROFESSOR OF SURGERY, NEW YORK SCHOOL OF CLINICAL MEDICINE; VISITING SURGEON, BETH ISRAEL HOSPITAL.

A. V——, aged twenty-eight years, furrier by occupation, native of Russia, came under my care at the Beth Israel Hospital on October 31, 1893. All the history bearing on his condition that could be obtained from him was that eight years previously he had had an abscess in the region of the left hip, which was then opened, and of which the scars are yet evident. Since then he has had no trouble from his hip. Otherwise he has been always well.

On admission to the hospital he was suffering great pain in the left thigh, extending from the buttocks to the knee, which pain was aggravated by pressure. There was then no apparent swelling, and only a slight rise of temperature. His trouble simulated sciatica, but on closer examination was found to be in the hip-joint, which was held slightly flexed, though at this time it was not dislocated. In the course of a few days a painful swelling began to form posterior to the hip-joint; the flexure of the thigh became much more pronounced. An abscess with spontaneous dislocation of the hip was diagnosed, and operative interference decided on.

On November 6th, a long incision was made over the trochanter major down to the bone, and the head was found in an abscess cavity above and communicating with the acetabulum. The head and neck of the bone were extensively carious, as was also the rim of the acetabulum, and excision was decided on. After freeing the periosteum, the ligaments were divided, except the teres which was already destroyed, and the head and neck were freed, protruded through the wound, and separated with a chain saw below the trochanter major. The lesser trochanter was chiselled off, the end of the bone rounded, and the carious portion of the acetabulum removed. The lower angle of the wound was sutured, leaving the major portion open for packing with iodoform gauze and healing by granulation.

The after-treatment was extension of the limb in abduction, and cleaning and repacking the wound every two or three days. About the eighth week the patient began to hobble around on crutches, with which, in the course of a couple of weeks, he got along very well. A shoe with an extra two inches of sole on that foot helped him to drop one and then the other crutch, and to walk pretty well without assistance. There was shortening of two inches, but a very good and serviceable joint, and six months after operation, when he was discharged from the hospital, the fistula had entirely closed and he was able to return to his work.

The head of the bone excised was entirely denuded of its articular cartilage; most of the surface was eroded, a segment of the under side rotted away, and on the upper side was a hole a half-inch deep, large enough to admit the tip of the index finger. The trochanter major was much enlarged and covered with spicula of new bone formation, apparently due to previous inflammation, and was also in some parts excavated and carious.

For the excellent skiagraph of this patient I am indebted to Dr. F. W. Gwyer, who has his apparatus at Bellevue Hospital. I believe it is the first taken showing, after so long an interval, nature's reparative

process in new joint formation. It was taken in January, 1899, more than five years after the operation, and shows excellently the truly wonderful formation of the new joint. The upper end of the femur has grown into a sort of mushroom-like expansion, very dense and solid on its inner side where it sits under the enlarged and projecting upper portion of the rim of the acetabulum. This portion of the acetabulum is also a very dense and solid bony growth, and from it extends a shelving process of new tissue, partly ossified, covering in the whole upper end of the femur. This new growth may be in process of further ossification to form ultimately a cap of solid bone over the new head of the femur. But for the present the weight of the body is evidently supported by the enlarged and projecting upper part of the rim of the acetabulum resting on the dense new bony growth on the inner side of the femur, and this is sufficient to give the man a good, freely movable, and serviceable joint.

While resection of the hip is quite a frequent and more or less successful operation for tuberculous disease in children, it is rather rarely done in adults, who bear the operation very badly. Ashhurst's statistics show sixteen per cent. of fatalities in children below fifteen years, and seventy per cent. in adults. I have been unable to find later statistics than his, given in 1888, but do not doubt that at the present time the mortality should be lower.

## BULLET WOUNDS OF INTESTINE; OPERATION; RECOVERY.

By GEORGE SHERRILL, M.D.,

STAMFORD, CONN.

On June 12, 1898, Joseph S——, an Italian, aged twenty-two years, was accidentally shot with a Winchester target rifle. The bullet (a 22 calibre, short), entered the abdominal wall at the right edge of the rectus muscle on a line between the umbilicus and right anterior superior spine of the ilium. He was taken to the Stamford Hospital, where I saw him two hours after he was shot. He was suffering from a moderate amount of shock, had a small regular pulse of 100, and complained of severe pain, referred to the region around the umbilicus. He was etherized, and, with the assistance of the hospital staff, I opened the abdomen in the right border of the rectus above and below the wound of entrance of the bullet. Beginning at the ileo-cæcal valve, I removed the small intestine, finding the first perforation about three inches from the cæcum. There were in all fourteen perforations of the small intestine, and one through the mesentery. Most of the blood found in the abdominal cavity came apparently from the wound in the mesentery, where an artery had been severed. The wounds of the intestine were sutured with a continuous suture through the mucous membrane, and two rows of Lembert sutures. The wound in the mesentery was drawn together by a continuous suture. The bullet was not found. The large intestine was apparently not injured. A very long appendix (normal) was removed. There was very little extravasation of the contents of the intestine in the abdominal cavity, which was washed out with a decinormal saline solution. A small wick of sterile gauze was left to drain through the wound of entrance of the bullet, and the abdominal wall was sutured. The operation consumed about three hours. The patient reacted well. The following morning he had a temperature (rectal) of 99.4° F. and a pulse of 90. He vomited but once. He had no nourishment by the mouth for seventy-two hours. His temperature did not go above 100° F., save on the third day when it reached 101° F. On changing the dressing I found a small amount of pus around the bullet wound, which apparently became infected from particles of clothing carried in with the bullet. His bowels moved on the fourth day without any help. The wound united primarily, save the sinus from the gauze drain, which filled up rapidly. The small amount of reaction that followed so extensive an injury to the intestine, and the rapidity with which the intestine recovered its tone, were remarkable. The patient, two hours before he was shot, had his supper, which consisted of three fried eggs, tea, and bread. He was operated on two hours after the accident, which happened three miles from the hospital, to which he was brought in a wagon, over a rough road.

## THE DRACUNCULUS MEDINENSIS.

By JOHN PATTERSON, M.D.,

CONSTANTINOPLE, TURKEY.

The *British Medical Journal* of January 23d contains a note on "Dracunculus Medinensis," by Dr. Major V. Harrington, I.M.S., in which he briefly discusses a few interesting points in connection with the habits of that parasite, and especially its wanderings in the body. The following case is somewhat illustrative.

A Frenchman, aged twenty-nine years, came under treatment on February 27th, for a large abscess of the left calf of the leg, which burst the same day by a very small opening. This was at once enlarged, and about two ounces of a pyosanguineous fluid escaped. The cavity was washed out with carbolic-acid lotion. For fourteen days it showed no sign of healing. An opening was then made in a more depending position, when a sinus, six inches long, was traced straight upward in the middle of the popliteal space. In almost a week or so, both the abscess and sinus healed. A few days later an œdematous red swelling appeared at the posterior part of the inner malleolus of the same leg, which was poulticed. It was opened the next day, March 19th, when a worm twenty-five inches long partly escaped, and was partly extracted. It had very feeble movements. The microscope showed the caudal extremity perfect, but no head. The wound rapidly healed.

The patient's history was as follows: The patient three years before had been on the Gold Coast for eighteen months, trading from Cape Coast Castle to Cape Palmas and Akra. He always went barefooted, and, with one exception, was never on shore. He returned to Havre, his native place. A year later, he shipped as foreman on board an English ship for Parmelio, on the Spanish coast. On January 6th, the ship called at Gibraltar for coal, where he scalded his right foot, and was sent next day to the hospital to be treated for the scald. He remained in the hospital thirty-six days, being discharged on February 12th. On February 1st, after living twenty days in the hospital, a hard, red swelling almost the size of a chestnut came out on the upper and inner part of the left tibia. This was poulticed for four days, and then "lanced" by a Spanish surgeon. "Bloody matter and four inches of a thin white worm came out." The wound healed in a few days, leaving a small circular cicatrix still visible.

The points of Major Harrington's note are that if the parasite be introduced into the system through the alimentary canal it would have insurmountable difficulties to encounter in finding its way to the extremities, especially to the lower part of the leg, in view of the anatomical "barriers between the abdomen and the thigh, and again those at the knee."

Now, in this patient the young dracunculus must have been taken into the alimentary canal in drinking-water, or introduced through the skin. In either case

(assuming that the parasite was acquired on the Gold Coast, as the other places frequented are not habitats of the dracunculus), it is remarkable how long was the period of development.

## TYPHOID PERFORATION IN A CASE IN WHICH THE WIDAL REACTION WAS ABSENT; OPERATION; DEATH.

By THOMAS W. JACKSON, M.D.,

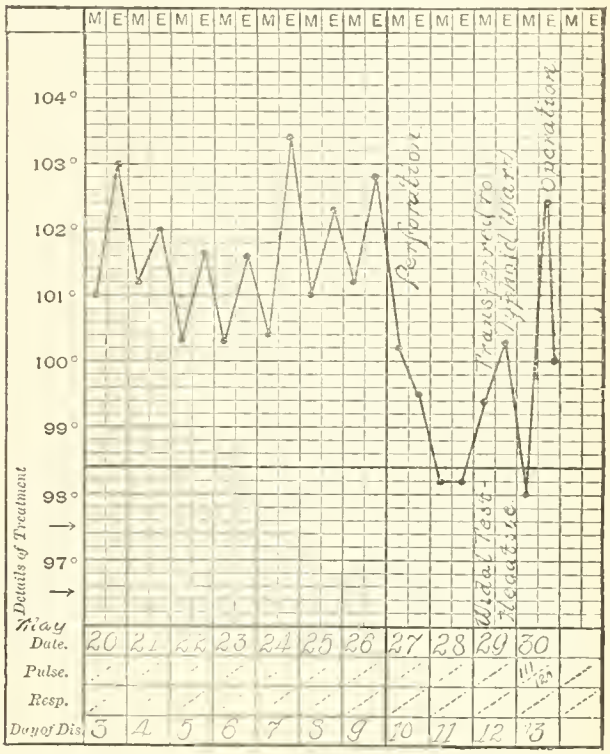
ACTING ASSISTANT SURGEON, UNITED STATES ARMY, PINAR DEL RIO, CUBA.

Operation in the case reported below may or may not have been well advised. Ordinarily the surgeon refuses to operate in any case in which the chances of a favorable outcome are so small as in this one, but the expressed request of an intelligent patient, that he be given the benefit of the only remaining chance for life, outweighed all other considerations in this case. Perhaps the most interesting feature is the lack of response in this case to the Widal test. This, however, can scarcely be used as an argument against the value of Widal's serum test in typhoid fever, as this case doubtless constituted an exception to the rule. An extended experience with the Widal test for diagnostic purposes has created in me a confidence in its value which this exceptional case has in no degree shaken. The case is as follows:

Private J. H. D——, Troop C, Seventh Cavalry, aged twenty-six years, was admitted to the post hospital, Pinar del Rio, May 20, 1899, suffering with fever of moderate degree. There was nothing significant about the condition of his bowels at the outset. Constipation and slight diarrhœa occurred, alternately at first, later followed by some pain in the abdomen. The tongue gradually took on an appearance suggestive of typhoid fever. Upon the 27th inst., a drop in temperature occurred (*vide* chart), with onset of hiccough and vomiting, but with a trifling amount of pain in the belly. No food was borne by the stomach, but small amounts of iced brandy and champagne were retained. It seems more than probable that perforation occurred May 27th, and that the hiccough and vomiting were referable thereto. Major S. P. Kramer, Brigade Surgeon U. S. V., of military hospital No. 2, Havana, chanced to be at this hospital May 29th, and concurred in the clinical diagnosis of typhoid fever, but subjected a specimen of the patient's blood to a careful microscopical examination for the malarial organism, and to the Widal test for typhoid, with negative result in each case. This finding left the diagnosis somewhat in doubt, and the symptoms of obstruction and peritonitis having become apparent, the possibility of an inflammatory condition surgical and non-typhoidal was considered. High colonic flushings failing to bring away any fecal matter, and the collapsed condition of the patient growing progressively worse, his desperate condition was explained to him; operation was offered and accepted, all with the knowledge that only the smallest chance of recovery, with or without operation, existed.

Major W. F. de Niedman and Acting Assistant Surgeons Alden, Bruning, Lundy, and myself concurred in the opinion that operation offered the only possible chance of recovery.

The patient went upon the table at 10 P.M., May 30th, with a pulse rate of 140. The anæsthetic was most carefully given and hypodermatic stimulation was continued throughout. The operation consisted of an incision over the cæcum, revealing adhesions and an abscess cavity in the right inguinal region. The abdominal cavity contained stinking gas and a considerable amount of brown fecal-smelling fluid. The abscess cavity contained about four ounces of pus. The small intestine was obstructed by adhesive inflammation of adjacent coils. The condition of the patient was so critical as to prevent further investigation, and the abdomen was quickly flushed with decinormal saline solution; the adhesions were separated, and the abscess cavity drained and walled off as completely as possible with gauze, the incision left open



and packed with gauze. The appendix vermiformis was inspected and found to be uninvolved and of normal appearance. The patient was taken from the table and lived for more than an hour. After death a further examination revealed typhoid lesions of the ileum, a perforation a quarter of an inch in diameter opposite to the abscess cavity, and a typhoid ulcer just upon the point of perforation, the serous coat of the small intestine alone remaining.

## WOOD PULP AS A MATERIAL FOR POULTICES AND SURGICAL DRESSINGS.

By FREDERICK T. GORDON,

HOSPITAL STEWARD, UNITED STATES NAVY.

I have for some time conducted experiments looking to the investigation of the properties of this substance, and I trust that the results here published will be of some practical use and value to the profession at large. Wood-pulp, as obtained in its crude form from the manufacturers, comes in sheets of any size and of varied thickness; it is comparatively cheap and easily obtained, and possesses the following valuable properties: When macerated in water, it swells up and absorbs from four to five times its weight of the liquid, retaining it for a long time. As the pulp becomes soft, a poultice of any desired consistence can be had by varying the amount of water. If hot water is used, the pulp absorbs so great a quantity that the resulting poultice will contain a greater proportion of hot water and retain its heat and moisture longer than a similar poultice made of bread or flaxseed. Antiseptic drugs soluble in water may be dissolved in the water in which the pulp is to be soaked, as the pulp is unaffected by most drugs of the sort. When perfectly dry the pulp will absorb oils and fats,

so that such antiseptics as thymol and eucalyptol can be dissolved in the oil and the pulp impregnated with the solution, giving an emollient and antiseptic substitute for salves, etc. (on lint), as a surgical dressing.

The pulp when moist can be moulded into any shape and will retain it when dry; it can therefore be used also as a splint.

When kept slightly moist with an antiseptic solution the pulp remains soft, and can be used as an absorbent dressing for wounds, ulcers, and suppurating surfaces.

Crude wood pulp, as received, can easily be sterilized by heating it in an ordinary sterilizer or oven. When heated sufficiently to char the surface slightly it will act as a deodorizing dressing.

For poultices, wood pulp is far superior to flaxseed, as it will retain more water (and consequently more heat), and thus the effect desired is produced with less trouble: the poultices can be prepared by simply soaking the pulp in water of the desired temperature, allowing the excess to drain, and then applying it. Pulp poultices thus made are far lighter than similar ones of flaxseed, and readily conform to the surface of the body; they require no cloths and no mixing, and can be made by the most unskilful nurse. Wood pulp is perfectly stable, does not deteriorate in any climate, and a supply can be carried in very small compass owing to its lightness; if wetted by any mischance, it can be dried in an ordinary stove oven. For the country practitioner it is the ideal material; no trouble, no mess, and the user can always be sure of getting exactly the results he wishes. Then it is very cheap, sheets four feet square costing no more than fifteen or twenty cents.

Navy Yard, League Island, Pa.

## Progress of Medical Science.

**The Plantar Reflex.**—In an article in *Brain*, No. 22, 1899, Dr. James Collier reports the results of certain investigations undertaken with a view to the elucidation of the nature and variations of the plantar reflex in normal persons, the character of the plantar reflex in diseases of the nervous system, the clinical value of deviations from the normal in such conditions, and a theory of the causation of pes cavus in spastic states. His conclusions from five hundred cases are as follows:

(1) This investigation has confirmed those of Babinski, Van Gehuchten, and Brissaud in all essential points.

(2) The plantar reflex of healthy subjects, with the exception of infants, consists of a regular succession of contraction in certain muscles to increasing stimuli. The response may be confined to certain muscles of the hip. It is doubtful whether the plantar reflex is ever constantly and completely absent in healthy subjects. The term "flexor response" is proposed for this form of plantar reflex.

(3) In infants, up to the age of learning to walk, the succession of the contraction of the muscles in the plantar reflex is entirely different from that seen in the adult; the change from the one form of the plantar reflex to the other occurring gradually with the establishment of complete volitional control over the legs, usually between the second and third year of life. The term "infantile response" is proposed for this form of plantar reflex.

(4) During sleep the plantar reflexes are diminished, and the infantile and adult forms preserved, except in some children up to the age of twelve years, in whom in deep sleep the infantile form of reflex returns.

(5) In almost all cases of lesions of the pyramidal systems, the form of plantar reflex is changed, a plantar reflex resembling closely that found in infants appearing. This change in the form of the reflex is one of the first signs of such lesions to appear, and is the last to disappear when the lesion is temporary. It may be the only unequivocal objective sign of a lesion of the pyramidal system. This form of reflex is never found under other conditions, and is a sign of great clinical value. The term "extensor response" is proposed for this form of the plantar reflex.

(6) In cases of total transverse lesion of the cord, the extensor response is the only reflex phenomenon present in the lower limbs.

(7) In functional cases the plantar reflex is often difficult to elicit, and there is frequently no response in the foot, but in such cases a response may usually be observed in the hip muscles. The form of reflex is the flexor response.

(8) In tabes dorsalis the plantar reflex was entirely absent in twenty per cent. of the cases. The response is often confined to the hip muscles. The attempt to obtain the reflex frequently may set up irregular movements of the foot lasting some time. The reflex when present is the flexor response.

(9) In peripheral neuritis the reflex when present is the flexor response. The hip muscles respond alone in some cases.

(10) In cerebral and cerebellar tumors the flexor response occurs if there be no involvement of the pyramidal system.

(11) In neurasthenia, chorea, paralysis agitans, poliomyelitis, myopathy, and sciatica the flexor response is found.

(12) In lesions of the pyramidal system a degree of pes cavus is frequently found. It is intimately associated with the extensor response in the plantar reflex, and is produced by a state of reflex hypertonicity preponderating in those muscles which respond most vigorously in the plantar reflex. In all such cases of pes cavus evidence of increased tone in certain muscles can be demonstrated.

(13) The theory that the pes cavus of spastic conditions is due to weakness of the interossei is not justified.

**Chronic Mediastinitis.**—Dr. William Cecil Bosanquet (*Lancet*, July 1, 1899) reports three cases of this disease occurring in the service of the Charing Cross Hospital, which present several points of resemblance and interest. The patients were all boys, their ages being respectively fifteen years, eight years, and six years. In one case there was a distinct history of ill-health dating from an attack of whooping-cough two years previously; in another, whooping-cough was the only disease from which the patient had suffered, and in the third case there was an anamnesis of measles. The writer calls attention to the frequency of enlargement of the bronchial glands in both measles and whooping-cough, and thinks it reasonable to conclude that the connecting-link between these diseases and mediastinitis may be found in a spread of inflammation from these structures to surrounding tissues. The duration of the illness after definite symptoms had developed was approximately two years in two of the cases. The third was of much longer duration. Clinically the most striking feature in each instance was the great enlargement of the liver, which was found to reach to or below the level of the umbilicus. In one case there was a definite history of recent rapid growth in size of this organ. The writer regards this enlargement of the liver as a valuable diagnostic feature, and says that in all cases of enlarged liver, especially in

children, without obvious cause the possibility of mediastinitis should be considered. Post mortem the condition of the liver was one of very chronic congestion, which seemed to have passed beyond the "nutmeg" stage into one of general engorgement, pigmentation, and fibrosis, with a certain amount of fatty change. In two of the cases the heart was small, the tough adhesions apparently preventing any great amount of dilatation or hypertrophy. All three cases might be classed as "mediastino-pericarditis," the pericardial cavity being almost completely obliterated. Pleurisy with effusion occurred in all three cases, and was bilateral in one case, and was of inflammatory nature. The kidneys were much congested. The urine always contained albumin toward the end of life. In none of the cases was increased cardiac dulness marked; recession of the intercostal spaces with cardiac systole did not occur, and no peculiarity of the pulse existed.

**Two Cases of Tabetic Spontaneous Dislocation at the Hip-Joint.**—Dr. Huchzermeyer reports, in the *Centralblatt f. Nervenheilkunde und Psychiatrie*, vol. xxvii., 1899, p. 263, two cases of tabes, in which dislocation of the hip-joint was an early symptom. Both of these patients showed typical symptoms of locomotor ataxia. The point of interest brought out in their clinical histories was that it was thought possible that the trauma was the cause of the development of the disease; the spinal cord becoming involved after a chronic ascending neuritis.

**The Origin of the Oxalic Acid of the Urine.**—As the result of clinical investigation Lommel concludes that the oxalic acid contained in human urine is derived, if at all, in only small amounts from the oxalic acid introduced with the food. In by far the largest part it is generated in the organism. The amount of oxalic acid in the urine and in the fæces after ingestion of considerable quantities of oxalic acid represents only a small portion of that introduced. The oxalic acid is probably decomposed largely in its passage through the organism. Decomposition of the oxalic acid in the intestines is, however, not to be excluded. The elimination of oxalic acid bears direct relation to albuminoid metabolism. A diet rich in nuclein induces, in addition to increased elimination of uric acid, also a considerable increase in the elimination of oxalic acid. A diet rich in gelatin likewise causes increased elimination of oxalic acid.—*Archiv fur klinische Medicin*, Nos. 5 and 6, vol. lxii., 1899.

**Purification of Water by Ozone.**—Th. Weyl, in the *Centralblatt f. Bacteriologie*, June 26, 1899, reports a series of experiments on the action of ozone on bacteria in drinking-water. These were carried on in the laboratories of Siemens and Halske, where the ozone was developed by electrical methods. The results would seem to show that the water could be rendered bacteria-free by this process, and in a large experimental research the plans were elaborated for the wholesale application of the process to purify the water of the Spree, furnished to the city of Berlin. The experiments carried on delivered 80,000 litres of ozonized Spree water in twenty hours, which water was as free from bacteria as the sand-filtered water utilized by that city. Organic matter was also considerably reduced in quantity by the process. The author suggests the use of such apparatus instead of the sand-filtration methods, since he believes the results obtained were better.

**Prophylaxis against Diphtheria.**—Gabritschewski (*Deutsche Medizinal-Zeitung*, August 14, 1899) mentions the following: (1) The bacteriological examination of the secretion of the mouth, pharynx, and nose must be undertaken not only in patients for diagnostic purposes, but also as a prophylactic measure in healthy persons who have been exposed to infection. (2) Infected persons, even though they are perfectly well, must undergo the same prophylactic measures as diphtheritic patients. That persons with a marked infection may appear perfectly well has been demonstrated by bacteriological investigation. (3) Patients who have been cured must not leave the hospital until the diphtheria bacilli have entirely disappeared. (4) In poor-houses, institutions, boarding-houses, as well as in families in which a number of children under ten years of age are to be found, a thorough examination of the mouth, nose, and pharynx for diphtheria bacilli must be undertaken yearly, preferably in the early spring. (5) The general disinfection in diphtheria cases must be done after the disappearance of the bacilli.

**The Femoral Artery and Vein.**—Dr. B. Merill Ricketts (*Journal of the American Medical Association*, August 12, 1899) concludes a short clinical and statistical article on "The Femoral Artery and Vein, Their Destruction Without Loss of Leg," as follows: (1) Amputation of the leg is not always necessary when the lumen of the femoral artery or vein, or both, is suddenly or slowly occluded by injury or otherwise. (2) It is better to ligate the femoral artery or vein, or both, and give the patient the benefit of a doubt, than to amputate immediately. (3) It is impossible to determine the circulation of the thigh or any given part of the human body without a complete dissection, which can be done only post mortem. (4) Ligating the femoral artery or vein, or both, in chronic pathologic conditions of the thigh, seems less likely to result in death or gangrene than when the ligature is applied in case of accident in a normal thigh. (5) It cannot be determined what rôle, if any, any one of the six varieties of the femoral artery has played in any case in which the femoral artery or vein, or both, have been ligated, as no record of dissection seems to have been made. (6) While end-to-end anastomosis may be accomplished, complete occlusion sooner or later takes place. (7) Suturing and the application of ligatures to arteries and veins which have been lacerated have no advantage over complete immediate occlusion by ligature. (8) Gangrene is possibly due to septic infection and not merely to the occlusion of the femoral artery or vein, or both, unless the vessels for collateral circulation are absent. (9) The preservation of the leg does not seem to depend upon the ligating of the femoral artery or vein, or both, at any particular point.

**Tabes Dorsalis.**—Dr. Adamkiewicz (*Berliner klin. Wochenschrift*, June 5, 1899) makes the following classification of tabes, according to the etiology: (1) Idiopathic, the usual and most frequent form, of unknown origin and incurable, resulting from a primary parenchymatous degeneration of the posterior column, and attended with progressive ataxia and grossly preserved muscular vigor. (2) Traumatic tabes, differing from the former only in its origin in trauma and the stability of symptoms. It is also incurable. (3) Syphilitic tabes, due to change in the vessels of the posterior columns of the cord, which are peculiarly susceptible to syphilitic changes. This variety is subdivided into two forms: acute, due to endarteritic processes, and curable; and chronic, dependent upon sclerotic processes in the posterior column, and hence incurable.

**Stricture of the Œsophagus.**—Dr. W. J. Mayo, in an interesting article on "The Œsophagus, Cicatricial Contraction Thereof; Its Treatment" (*Journal of the American Medical Association*, July 29, 1899), formu-

lates the following conclusions: (1) Systematic sounding should be commenced in from two to four weeks after the swallowing of a caustic substance. (2) Should the traumatism be severe, immediate gastrostomy will lessen infection and hasten cicatrization, sounding being carried on as before. (3) Non-dilatable strictures in the vicinity of the cricoid cartilage should be divided by external œsophagotomy. (4) Stricture above the arch of the aorta may be safely cut by a combined internal and external œsophagotomy. (5) Dense thoracic strictures are best dilated by Ochsner's method, and, if necessary, divided by Abbe's string saw. (6) Impassable strictures should be treated by retrograde dilatation. (7) A dilated stricture should be occasionally sounded for years, if not for life.

**Typhoid Fever in Army Camps.**—In an article on "My Observations on the Typhoid-Fever Epidemic in Southern Camps and Its Treatment" (*New York Medical Journal*, August 5, 1899), Dr. Joseph F. Chmelicek, from a personal experience, arrives at the following conclusions: (1) The camp should be frequently changed. (2) The division hospital is here to stay, as only in this hospital can female nurses be employed, and (3) the proper person as attendant is the female nurse. (4) All soldiers should be educated in plain sanitary hygiene. (5) The sooner the patient takes to bed the fewer complications are likely to follow. The hemorrhagic and perforation complications develop in patients who walk until they fall, and who use indigestible food during the first stage of typhoid. (6) Milk is not suitable for every case; many of the patent foods on the market, especially "predigested" foods, must replace it in many cases. (7) Sugar used during convalescence will cause relapse quicker than solid food. (8) Every case requires special study. (9) The severest case, with hemorrhages and other complications, may be recovered from, while the lightest case, apparently doing well, may result fatally. Never give up a case as hopeless. (10) All the patients in the southern camps showed a remarkably low pulse rate even with high temperature, for which I cannot offer any explanation.

**Successful Resection of Carcinoma of the Liver.**—Keen has reported the case of a man, fifty years old, who for three months complained of dull pain in the abdomen just below the umbilicus and also in the epigastrium. The pain was moderately severe, and for a time transient, but subsequently it became almost constant. It was of a dull, grinding character, and it increased after meals. The appetite had been poor for two months. There was, however, no nausea or vomiting. The bowels were moved daily, and the stools were normal. The man had previously weighed two hundred and thirty-five pounds, but he had been reduced to two hundred and five. He was weak and had been incapacitated from work for ten weeks. On uncovering the abdomen the epigastrium was seen to bulge forward in a uniformly rounded swelling. The elevation above what would be the normal contour of the abdomen was 2 or 3 cm. in size. Palpation disclosed a hard, firm, movable mass, the size of a large hand, entirely filling the epigastric region, and extending to the level of the umbilicus. Over this the percussion note was dull and the dulness was continuous with that of the liver. With the gastrodiaphane the epigastrium appeared absolutely opaque. Hydrochloric acid was found in normal proportion in the gastric juice obtained after a test meal. There had never been jaundice or other hepatic derangement, and no disturbance of the bowels. An exploratory operation was advised and consented to. As soon as the abdomen was opened in the middle line it became clear that the tumor was hepatic, and when it was drawn outside of the abdomen a number of large nodules were found occupying the entire left lobe of the liver. Palpation failed to disclose other nodules or involvement of the lymphatic glands. As it seemed possible to remove the entire left lobe of the liver, and with it the whole of the tumor, extirpation was at once proceeded with, the operation being performed entirely with the Paquelin cautery. From twenty to thirty minutes were required to sever the left lobe from the remainder of the liver. The hemorrhage was not excessive, except when some of the larger veins were burnt into. Each of these when opened was instantly closed with the left forefinger; then, with the cautery temporarily laid aside, a catgut ligature was passed under each by means of a Hagedorn needle, and an assistant tied it slowly but firmly. Five ligatures were thus applied. Three of the veins required ligature of both of the divided ends. The hemorrhage, except from these large veins, was arrested by the Paquelin cautery; however, occasionally, when the cautery was laid aside to apply the ligature, temporary packing with iodoform gauze proved of great service in arresting the parenchymatous hemorrhage. The amount of blood lost was estimated at eight or ten ounces, but as a severe loss was feared before the end of the operation, an intravenous saline injection, one quart, was made at the beginning of the hepatic portion of the operation. The surrounding tissues were well protected against the cautery by wet aseptic gauze pads. When the tumor was removed it was found possible to obliterate a part of the resulting raw surface by folding the edge of the liver upon itself like the flap of an amputation, the cautery incision having been made obliquely. A few catgut stitches approximated these flaps, but there was still left over one half of the burnt surface exposed in the peritoneal cavity. To prevent hemorrhage or subsequent adhesions, as well as to provide against the escape of bile into the peritoneal cavity, iodoform gauze was packed against the liver, the end protruding through the abdominal wound. The abdominal cavity was then carefully flushed out with salt solution, though but few clots were thus removed, and the abdominal wound was closed excepting at the point where the gauze packing protruded. The tumor measured five and one-half inches long, four and one-quarter inches wide, and three inches thick. Its circumference was eleven by thirteen and one-eighth inches in the two directions. The raw surface left where the tumor had been detached from the liver was five and one-half inches by two and three-eighths inches. The weight of the tumor was twenty-one ounces. The post-operative history was uncomplicated; with the exception of vomiting, which continued for nearly forty-eight hours, and hiccough on the second day, nothing of special note occurred. Ice, champagne, doses of cocaine, gr. $\frac{1}{40}$, and similar doses of carbolic acid had no effect on the vomiting. At the end of forty-eight hours, after lavage, both the vomiting and the hiccough ceased entirely. The temperature scarcely rose above the normal. The gauze packing was removed at the end of forty-eight hours. It was stained in streaks with bile. By the fourth day the discharge of bile through the opening left by the removal of the gauze was quite free, amounting to perhaps three or four ounces in twenty-four hours. This gradually diminished, and ceased by the twelfth day, a little serous discharge then taking its place; but this became slightly purulent after two weeks. After a month the wound was entirely well except for a small shallow sinus, which promised to close, and the patient was out of bed. Histological examination disclosed the tumor to be a carcinoma.—*Annals of Surgery*, No. 3, vol. xxx., 1899.

# MEDICAL RECORD:

WM. WOOD & CO., 51 Fifth Avenue.

New York, October 7, 1899.

## DRAINAGE AFTER SUPRA-PUBIC CYSTOTOMY.

THE more nearly we approach perfection in any surgical procedure, the more distinctly are emphasized any imperfections in the details of technique or result. There was once a time when supra-pubic cystotomy was looked upon as a dangerous and undesirable operation. This period was followed by one during which the pendulum swung the other way, perhaps too far, and at present there are frequently urged several more or less serious drawbacks to the operation, though no satisfactory substitute is offered. The question of proper drainage is the one about which there is most discussion, without any very definite agreement among surgeons.

The most generally advised methods of securing bladder drainage are through the supra-pubic wound by means of some sort of a tube or even a siphon. The disadvantage of drainage by this route is that fluids persist in declining to run up hill, and in order to escape in this way there must be some *vis a tergo*. The dressings are troublesome, and our success is only partial in getting rid of the discharges, some of which remain in a bladder already the seat of inflammation varying in severity from the least to the greatest. The effect of this retention can only be to maintain and increase the amount of inflammation, which depends as a rule upon qualities in the urine as it enters the bladder or acquired by it while in that organ.

If we add to these sources of irritation the effect of the operative traumatism and the possible invasion of bacteria from the air or other surroundings, it is easy to understand what may be important factors in delaying the healing of a supra-pubic wound, especially toward the end of its course when conditions become so favorable for the formation of a fistula. This is in sharp contrast with the behavior of the perineal opening into the bladder, made for the purpose of drainage, after a deep urethrotomy for instance, when the intra-vesical conditions may be fully as bad as in disease requiring the supra-pubic operation. It is unfortunately too common an occurrence, after the latter operation, to have the wound apparently go on to solid healing, and then break open and establish a fistula into the bladder. The reason for this occurrence is certainly not to be found in the skin, fascia, and muscle, but is to be sought in the wall of the bladder and in the cavity of the organ. The mucous membrane of the anterior vesical wall is loosely attached, and its relations are more or less disturbed when the bladder is opened in this region, so that there is a chance for infection and inflammation between this membrane and the rest of the wall. After the operation is complete, conditions are not favorable for accurate suturing even if such were desirable, and when supra-pubic drainage is established the edges of the wound are continually covered with urine and pus which act as irritants and interfere with normal healing. The explanation of fistula-formation after apparent solid healing can be found in the mucous membrane at the point where the wound should finally heal. Instead of a prompt re-formation of mucous membrane along the line of incision with very little cicatricial tissue, there is more or less irregularity in the process, and the formation of granulation tissue which is destined ordinarily to become dense cicatricial tissue, but which under these circumstances is perverted from this course. The result of this is the formation of one or more points of unhealthy and sluggish granulation in the interior of the bladder, along the line of the incision, any one of which may give entrance to bacteria practically always present in the urine of these patients. It is then a short step to abscess and fistula and perhaps extensive infection in the cellular tissue of the abdominal wall. The addition of a perineal drain makes the prospect of getting solid and prompt union in the supra-pubic wound much greater than if up-hill drainage is depended upon, and the introduction of such a drain is an easy and rapidly accomplished matter. This form of drainage is particularly satisfactory when the bladder is the seat of chronic inflammation, to ameliorate which it is desirable to give the organ complete rest. With the perineal tube carefully kept open by suitable irrigation, the course toward healing in the supra-pubic wound is much more satisfactory, and on this account this form of drainage should be recommended as a routine procedure in cases of supra-pubic cystotomy, to be discarded only under exceptional circumstances. The annoyance of a persistent supra-pubic fistula can hardly be overestimated, and, furthermore, its presence involves a certain amount of danger. We are therefore justified in using perineal drainage simply because it increases the chance of permanent recovery, not because it is demanded by any specific intravesical condition. This plan is already carried out by some surgeons in their intravesical work, and its adoption will probably become general, as its desirability becomes recognized.

**Another Model Dwelling-House for London.**—The homes for the working classes in London introduced by Lord Rowton have proved so successful in every way that new ones are being built in all parts of the metropolis. It is stated that a Rowton House is to be built in the heart of the East End, in Whitechapel, behind the London Hospital. Accommodation will be provided for eight hundred inmates.

## VENTILATION AND SANITATION OF CHURCHES, THEATRES, AND RAILWAY CARS.

Sir William Preece, in the course of his presidential address delivered at the meeting of the British Sanitary Institute, recently held at Southampton, referred to this subject, which was a few months ago made the text for an editorial in the Medical Record and which attracted widespread attention. Sir William Preece spoke as follows: "Thus the whole theory of ventilation is circulation of air maintained at a proper temperature, for cold air may be injurious. The British legislature has taken care that lunatic asylums, hospitals, workhouses, and jails shall be well supplied with proper air space per person, and shall be supplied with effective means for ventilation; but churches, theatres, meeting halls, assembly rooms, railway carriages, and other places where healthy and well-to-do persons most do congregate are totally neglected and remain sinks of discomfort." This evil exists probably to quite as great an extent in this country as in Great Britain, and now that the theatre season has just commenced, the time for once again attracting notice to this unpleasant state of affairs is distinctly apropos. As was stated in the article in the Medical Record, the initiation of sanitary reforms in theatres rests wholly with the public. Until the patrons of theatres show their dissatisfaction with the present sanitary conduct of play-houses in a practical manner, the proprietors thereof are not likely to make a move. If, however, theatre-goers decide to boycott those theatres which are notoriously defective in ventilation and general sanitation, the result will be that a radical change will quickly be brought to pass. Similar remarks apply with equal force to railway cars. So far as churches are concerned—although in many good hygienic arrangements are woefully lacking—the remedy is more difficult to suggest. Nevertheless the majority of American churches are supported by their congregations, and if these congregations refuse to endanger their health by attending services in buildings in which the sanitation is bad, the result would doubtless be that the causes of offence would be forthwith removed and the defects put in order.

## CRIMINAL PRACTICE IN SEARCH OF PROTECTION.

It is not so many years ago that there lived in New York a man of unsavory reputation who was wont at stated intervals to send his professional card broadcast in the community heralding the fact that he was a specialist in obstetrics, and offering his services to such as had "sinned without right," or who, having the right, were not willing to accept the consequences. For years this man prospered in the community, a professional abortionist, protected by police and officers of the law. The Medical Record over and again scored the fellow, and finally he fled the city under indictment, doubtless with sufficient of (in his case) filthy lucre to live and prosper the rest of his days. It is inevitable, apparently, that the abortionist should ply his trade in every community, for he is, of all foul birds, the one it is most difficult to salt the tail of. In other words, legal proof is hard to secure for self-evident reasons. And yet in view of the ills, moral and physical, following in the train of the abortionist, every community should aim at ridding itself of him. At least, let him keep under cover and not inflict on the medical fraternity his alluring circulars, filled up with insulting proposals. These remarks are called for by the receipt of a circular from one who aims at being the successor of "the man with the card." This circular, after alluding to the advantages offered at his sanatorium, offers a bonus of twenty per cent. to the practitioner referring a case for "treatment," thus making him a party to the act, and securing for the proprietor of the sanatorium the further protection of being backed by medical men of supposedly good repute! Will the fish bite? Gullible as the profession has often proven itself to be; ready as over and again it has shown itself to be to help boom some patented article which is later advertised in the lay press and travelling conveyances; blind as repeatedly it has been to its own interests, it remains to be seen if this latest bid for protection, together with its insulting proposal, shall meet with the ready response it calls for.

## AN ATTACK ON BACTERIOLOGY.

Of all the subjects discussed at the recent meeting of the British Medical Association, that on the relations of bacteriological research and methods of treatment to preventive medicine, dealt with by Dr. George Wilson in the opening address of the section of state medicine, was one of the most valuable. Its interest lay in its revolutionary character. The address was from beginning to end a strong indictment of the manner in which bacteriological research is carried on by present-day investigators, and, according to Dr. Wilson, the erroneous premises deduced from these investigations. After offering up the usual meed of praise to Jenner—we are pleased to observe that Dr. Wilson is a firm believer in the efficacy of vaccination—he proceeds to show, at least to his own satisfaction, that the modern bacteriologists, while admitting that they base their methods of prophylaxis and cure on Jenner's discovery, ignore the important point that no pathogenic microbe of smallpox or vaccinia has ever been isolated with certainty. He, therefore, argues that there is no legitimate analogy between Jenner's discovery and these newer methods of prophylaxis and cure founded on that discovery. Dr. Wilson furthermore contends that the almost universal use of antitoxins by the younger generation of medical men is chiefly responsible for the existing widespread prejudice against vaccination; in fact, he claims that the members of the medical profession have to a great extent only themselves to thank for the present unfortunate situation. The latter portion of the address is taken up with the endeavor to demonstrate the worthlessness of most of the cura-

tive serums and of the mode of procedure of many experimental operators, and concludes with a vehement diatribe directed against the commercial methods of a considerable number of up-to-date bacteriologists.

While we cannot accept these conclusions, the expression of such views is not without its uses. There is a certain amount of danger in keeping our eyes fixed too steadily on bacteriology alone, and, wonderful though its revelations be, we must not let them blind us to other causes or favoring factors of disease. Medical progress nowadays has been compared to the rush of a railroad train, and it must be allowed that on occasions the presence of a brake is needful, and to that useful instrument for impeding the too rapid revolution of the wheels the address of Dr. Wilson may not be unfairly compared. His opinions, like those of most earnest critics, have a decidedly biassed tone, and his sweeping assertions as regards the absolute uselessness of bacteriology will hardly carry conviction to the minds of the unprejudiced. At the same time it is possible that enthusiastic bacteriologists have been transported by the vehemence of their beliefs, and have lauded in extravagant and absurd terms the virtues of the serum treatment. We are, however, cordially in accord with Dr. Wilson when he attacks the commercial aspect of the question, and agree with him that the action of Behring and Koch is altogether at variance with professional ethics.

## NEGRO MORTALITY.

Attention has again been called to the extremely high death rate among negroes. Since the abolition of slavery the colored race has decidedly retrograded from a health point of view. This is undoubtedly chiefly due to the unsanitary conditions under which the majority of negroes live. In the Southern towns they are herded together in alley tenements whose unhygienic state and want of cleanliness tend to originate and spread disease. The existing state of affairs is a standing menace to the health of the community at large, and calls for immediate reform. At the Hampton Conference held in July, Dr. F. J. Shadd, of Washington, gave statistics regarding the mortality of the negro in Southern cities. In Baltimore for a given period among the whites the proportion of deaths was slightly less than that of births. Among the colored the deaths were greatly in excess of the births. Deaths from scrofula and consumption are twice as numerous with the colored as with the whites. The most rapid increase in the death rate has been among infants. But while this side of the picture is dark, the gloom is relieved to a certain extent by the knowledge gained by the committee of investigation, showing that the growth in material prosperity among the negroes is satisfactory. With the accumulation of property, together with the sense of responsibility which the possession of money brings, and with the advance of education, it is to be hoped that a new era may dawn for the negro, and that in the course of time he will develop into a clean-living, self-respecting citizen.

## News of the Week.

**Tri-State Medical Society of Alabama, Georgia, and Tennessee.**—The eleventh annual meeting of the Tri-State Medical Society will be held in Chattanooga Tuesday, Wednesday, and Thursday, October 24, 25, and 26, 1899. Those desiring to read papers should send titles to the secretary, Dr. Frank Trester Smith, Chattanooga.

**Medical Society of Virginia.**—The thirtieth annual session of this society will be held in the roof garden of the Jefferson Hotel, Richmond, Va., October 24, 25, and 26, 1899, under the presidency of Dr. Jacob Michaux, of Richmond. The recording secretary is Dr. Landon B. Edwards, and the corresponding secretary Dr. J. F. Winn, both of Richmond.

**Insurance against Sickness.**—In 1889 a law was passed in Germany that every German with an income of $750 and over must insure his life against sickness and old age. In 1898 there were 11,200,000 persons in Germany thus insured, and so many of these had pulmonary consumption that thirty-seven of the insurance companies erected at their own expense a sanatorium for the care of these persons.—*Maryland Medical Journal.*

**Osteopathy in South Dakota.**—At a meeting of the South Dakota State board of health, held recently at Sioux Falls, a decision was made concerning the licensing of osteopaths to practise in the State. It was resolved that only graduates of "regularly conducted" schools of osteopathy should be admitted to practice. The requirements of such regularly conducted schools were stated to be as follows: (1) The possession of a diploma or certificate of graduation from a high school or a certificate of successful examination in certain branches equivalent to a high-school course. (2) One course of twenty months' duration or four courses of five months' duration each in anatomy, physiology, chemistry, histology, theory and practice of osteopathy, pathology and pathological anatomy, and obstetrics and gynecology. In addition evidence must be given of attendance upon at least two terms of clinical instruction and of having dissected at least one lateral half of a cadaver. Finally, the school must show that it has a sufficient and competent corps of instructors, and the necessary facilities for teaching by laboratories and clinics, and for dissections.

**Pathological Society of Philadelphia.**—At a stated meeting held September 28th, Drs. A. A. Eshner and G. A. Pfahler presented two hearts, one exhibiting the lesions of chronic endocarditis, together with recent vegetations and ulceration, aneurism of a sinus of Valsalva, and obliterative pericarditis; the other extensive atheroma of the aorta and of the aortic and mitral valve leaflets. The case from which the first specimen was obtained presented distinctive features, and was recognized during life as one of ulcerative endocarditis; that from which the second specimen was obtained simulated ulcerative endocarditis, being

complicated by a purpuric eruption, gangrenous stomatitis, hemorrhage from the mucous membrane of the mouth, and icterus, but chills, sweats, and elevation of temperature were wanting. Dr. J. H. McKee exhibited a bilocular dermoid cyst of the ovary removed surgically from the abdomen of a child seven years old. In the growth epiblastic and mesoblastic structures were found. Dr. D. Riesman exhibited an abscess of the right frontal lobe of the brain in an adult woman, without obvious ear disease, or nose disease, or disease of the cranial bones. There was no history of recent traumatism or of syphilis, and no evidence of any other focus of suppuration, although a complete post-mortem examination was not permitted. The abscess was well circumscribed, and contained offensive greenish pus. Dr. M. H. Fussell exhibited specimens of croupous pneumonia, of enlarged spleen, and of chronic nephritis, from an alcoholic subject whose blood during life yielded the Widal reaction, although he presented no symptoms of typhoid fever and gave no history of a previous attack, and the intestines were free from lesions.

**Philadelphia County Medical Society.**—At a stated meeting held September 27th, Dr. A. A. Eshner presented a case of myxœdema in a man, fifty-four years old, in which improvement followed administration of thyroid extract, gr. v. daily.

**Hospitals Not Liable for Damages for Unauthorized Autopsy.**—A Philadelphia judge, in refusing a new trial in a suit for damages against the German Hospital, has decided that as a public charity, possessed of no funds except such as have been contributed by the charitably disposed for the furtherance of its philanthropic purposes, the diversion of its assets to compensate for injuries inflicted or occasioned by the wrongful acts of its agents or servants would be against all law and all equity.

**The Schleich Method of Local Anæsthesia.**—In discussing the methods of producing extensive local anæsthesia with Schleich's solutions, Dr. Rudolph Matas stated before the Orleans Parish Medical Society, September 23d, that the injection of the solution directly into the nerve trunks by the "blocking" method gave the most satisfactory results. Such a procedure is not applicable in every case, owing to the difficulty of exposing the nerves, but in all operations of any magnitude upon the extremities, *e.g.*, amputations, resections, etc., the anæsthesia is all that could be desired.

**The Plague** continues without much change in all the places where it has been previously reported to exist. In Poonah, in the Bombay Presidency, it has begun to attack the European residents, even those who have not, as nurses or physicians, been brought into immediate contact with plague sufferers. Twenty physicians and thirty nurses have recently been sent to India from England on special plague duty. The disease in southern Russia is said to be of the pneumonic form, and fears are entertained of its spread to other parts of the empire. The Paris newspapers publish reports of an interview with Dr. Calmette, who was sent by the Pasteur Institute to study the outbreak in Oporto, in which he says that before his arrival the mortality among those stricken with the plague amounted to thirty-three per cent., whereas, of fifteen treated by him with Yersin's serum, not one died. This restored public confidence, and in three days he inoculated four hundred and twenty-three persons. Dr. Mendoza, who was sent by the Spanish government to study the disease in Oporto, has reported that the plague owes its virulence to the filthy dwellings and habits of the people living in the poorer parts of the city. Those attacked are conveyed to the Misericordia Hospital, and none of the hospital patients were found to constitute new foci for disease, demonstrating the facility with which the epidemic might be localized and stamped out if energetic measures were adopted. The disease has spread from Oporto to Bagina, a village outside the sanitary cordon, and several of the soldiers forming the cordon have been stricken. Several of the foreign physicians who have gone to Oporto to study the disease were recently stoned by a mob and were rescued with difficulty by the police.

**The Hospital Ship "Missouri"** has recently sailed from this port for Manila. She was formerly of the Atlantic Transport Line, and is the finest ship in the hospital service.

**Dispensary Management.**—The committee on dispensaries of the State board of charities gave a public hearing in this city a few days ago, at which a tentative set of rules for the government of dispensaries was discussed. Those rules were based upon data obtained from physicians and laymen engaged in the administration or supervision of dispensaries, and the committee wished to obtain further suggestions before submitting the rules to the State board. One of the rules provided for a minority representation of women on the managing boards of dispensaries incorporated independently of any other institution. The main objection offered to the adoption of this rule was that it might possibly conflict with the provisions of some will or charter under which the dispensary might have been established. On the other hand, others argued that this requirement was entirely in accord with an increasingly prevalent sentiment that institutions treating women and children should have women members in the supervising body. Another rule which elicited considerable discussion was one which seeks to provide a means of sifting out of the number of applicants those who are able to pay for medical attendance. The rule requires that all applicants shall sign a sworn statement of their inability to pay, and that all suspicious cases shall be investigated. It was thought that in time there would be established a registration bureau, which should act as a sort of clearing-house, wherein should be filed a list of all applicants for treatment, together with the results of an investigation concerning their financial ability.

**A School for the Feeble-Minded.**—"The Chicago Physiological School" has recently been incorporated under the laws of the State of Illinois by President

Harper of the Chicago University and others. The school is to be an experimental one in training children whose development is stunted. There will be three departments, physiological, psychological, and pedagogical. Those who are to be in charge of the school will keep the pupils under constant surveillance. A close study is to be made of the peculiarities of each one, and records of every observation will be kept. It is thought by this method to get at some logical conclusions to determine what environment will do for the children who fail to develop normally. It is thought probable that the school, if it turns out to be practically successful, will eventually become affiliated with the University of Chicago. The school will be under the charge of Miss Mary R. Campbell, who is also one of the incorporators.

**Death of the Tallest Man in the World.**—Harry Cooper, said to be the tallest man in the world, has just died. He was born at Cleveland, in Yorkshire, England, and was eight feet eight inches in height. He was at one time a member of Barnum's troupe, and died in British Columbia.

**Deportation of a Leper.**—The health authorities in San Francisco are having trouble with a woman who is in an advanced stage of leprosy, and whom they desire to send to Hawaii in an army transport. The woman objects to being deported, and has appealed to the War Department officials in Washington, with the result that some other means of transportation will have to be provided if the woman is to be sent to Molokai.

**Yellow Fever** continues at Key West in undiminished force, the number of new cases being from forty to fifty daily. Sporadic cases have occurred also in Jackson, Miss., and it is probable that a quarantine will be declared against the town. The yellow-fever report for September has been made public in Havana, showing a total number of fifty-four cases, with eighteen deaths. The weather is now cool, and no more apprehension is felt. It is thought remarkable that in Casa Blanca, formerly the worst part of the city, there was only one case of yellow fever during the month.

**The Association of Military Surgeons.**—The eighth annual meeting of the Association of Military Surgeons of the United States was held in Kansas City last week. Delegates were present from Great Britain, Mexico, and all parts of this country. At the opening session addresses of welcome were made by Major Jones and Major William Warner; Medical Director Capt. J. W. Woods, U. S. N., and Col. Nicholas Senn, Surgeon-General Illinois National Guard, responding. Col. Henry Lippincott, formerly chief surgeon of the army in the Philippine Islands and now in charge of the department of Colorado, spoke on "The Army." One of the papers which caused the liveliest discussion was presented by Dr. Huidekoper, formerly a veterinary surgeon of this city and later surgeon of the First Army Corps. The paper, entitled "The Organization of Army Corps," was essentially a defence of the volunteer surgeon as opposed to the regular army surgeon in the management of the home camps during the late war. Concerning the regular army surgeons, "while," he said, "they were mostly officers of ability and reputation, there were among them men who never, in last year's war, learned to appreciate that an army corps was larger than any one company post in which they had been stationed in the last decade or more, and who absolutely failed to realize the energy and attention required for the handling of new troops." He spoke of the difficulty experienced in getting medical supplies, and declared, "The complete outfit of a brigade hospital as a unit, and the supplies for three regiments multiplied a hundred times, could have been supplied by any contractor inside of two weeks." He said that while at Chickamauga he had made many complaints of the men forced upon the surgeons as nurses. Numbers of these were epileptics and drunkards whom the line officers transferred to the hospital corps in order to get rid of them. His complaints were pigeonholed, however, and never bore fruit.

**Obituary Notes.**—Dr. Israel Gilbert Young died at Philadelphia, on September 27th, at the age of fifty-nine years. He was graduated from the medical department of the University of Pennsylvania in 1862. —Dr. Henry C. Cunneely, of Hoboken, health warden of the city, died on September 30th, of appendicitis. He was graduated from the Bellevue Hospital Medical College in 1886, and then served the regular term on the house staff of St. Vincent's Hospital.— Dr. George W. Wayson, of Baltimore, died in that city on September 26th, at the age of eighty years. He was a graduate of the Washington University School of Medicine, Baltimore, in 1846. During the Civil War he raised a regiment on the side of the Union, and was its colonel. Afterward he was elected to the city council, and while there introduced the bill to establish the first free school for colored children. —Dr. John Henry Fuess, an acting assistant surgeon in the United States army, stationed at Santiago, committed suicide last week while on the transport *Burnside*, arriving at this port from Cuba. He had hallucination of persecution, and in a letter written just before he shot himself, Dr. Fuess wrote that he had been permitted to practise privately in Santiago, and that he was doing well until another physician appeared in his neighborhood, and formed a conspiracy with his colored servant to ruin him. He said that the physician and the servant accused him of suppressing a case of yellow fever, and although the charge was false it ruined his reputation. Dr. Fuess was a native of Germany, and was thirty-five years old.—Dr. Francis A. Thomas died in the Presbyterian Hospital, New York, on October 1st, from concussion of the brain, having been struck by a cable car a few days before. He was born in Lewis County seventy-three years ago, and was graduated from the College of Physicians and Surgeons in 1853. The next year he was appointed house physician and surgeon on Blackwell's Island, and he served one year. In 1868 he was appointed a police surgeon, and he held the position for ten years.

# Reviews and Notices.

DIAGNOSTIC DES MALADIES DE LA MOËLLE (siège des lésions). Par le DR. GRASSET, professeur de clinique à l'Université de Montpellier, associé national de l'Académie de médecine, lauréat de l'Institut. Paris: J. B. Baillière et Fils. 1899.

IN this little volume there is presented concisely the diagnostic symptomatology of the diseases of the spinal cord, with especial reference to the distribution and the localization of the lesions. The matter is considered in two main parts: (1) the diagnosis of the system or tract affected, and (2) the diagnosis of the level of the lesion. Under the first division there are discussed: the symptom complex of disease of the posterior columns—disturbances of sensibility and of co-ordination; of the antero-lateral columns—paresis, spasticity, contractures, and intention tremor; of the posterior and lateral columns—ataxia and spasticity; of the anterior horns—muscular atrophy; of the lateral columns and the anterior horns—muscular atrophy and spasticity; of the central gray matter—syringomyelic sensory dissociation and vasomotor disturbances; of the anterior horns and the central gray matter—muscular atrophy, syringomyelic dissociation, and vasomotor disturbances; and of a lateral half of the cord—crossed hemiparaplegia. In the second part are discussed first the general principles governing the diagnosis of the level of the lesion, then the root and segmental symptoms of lesions of the conus medullaris, and successively of the sacral, lumbar, dorsal, and cervical portions of the cord. This exposition should prove useful to both clinician and surgeon, as some of the disorders under consideration are not amenable to medicinal measures and will require operative intervention.

LES GREFFS URETÉRALES. Par DR. P. TREKAKI. Paris: A. Maloine, Éditeur. 1899.

THIS little monograph embodies a very full discussion of the occurrence, production, treatment, and results of fistulæ between the ureter and other structures or the external air. The absence of illustrations and diagrams does not help the descriptions of operative work, but the discussion of indications, etc., is clear and systematic.

THE TREATMENT OF PELVIC INFLAMMATIONS THROUGH THE VAGINA. By WILLIAM R. PRYOR, Professor of Gynæcology, New York Polyclinic, etc. With 110 illustrations. Philadelphia: W. B. Saunders. 1899.

THIS is a series of lectures, elaborated and put into book form. The author is a firm believer in the efficacy of the treatment of many conditions in the female pelvis by the vaginal route, and he cites many cases in support of his views. There is no doubt that operation through the vagina has in skilled hands many advantages over the abdominal method, especially remote advantages, but it is also true that the vaginal method is not one so much easier than the abdominal that its employment should be recommended without special instruction in the details of its technique. The book contains many useful hints for the advanced student, and much that is interesting and useful for one who is specially interested in gynæcology. There is a well-written and freely illustrated chapter upon vaginal ablation.

THE CEREBRO-SPINAL FLUID; ITS SPONTANEOUS ESCAPE FROM THE NOSE. With Observations on its Composition and Function in the Human Subject. By ST. CLAIR THOMSON, M.D., M.R.C.P. Lond., F.R.C.S. Eng.; Physician to the Throat Hospital, Golden Square; Surgeon to the Royal Ear Hospital, London. 8vo, pp. 140. London, Paris, New York, and Melbourne: Cassell & Co., Limited. 1899.

WE have here presented the interesting account of a case in which discharge of cerebro-spinal fluid took place spontaneously from one side of the nose for a period of several years, together with a collection of twenty other cases in which it is believed a similar condition was present, though, as a rule, not recognized. The patient whose case is reported in detail was in apparently good health, and free from any tangible cause for the rhinorrhœa, suffering only in consequence of the mechanical disability; although in most of the other cases cerebral symptoms were present and in some retinal changes. A description of the composition and function of the cerebro-spinal fluid in the human subject, based upon careful studies, is also given. Escape of cerebro-spinal fluid as a result of traumatism is a well-recognized phenomenon, but spontaneous discharge has hitherto received scanty recognition. The only plausible explanation of either condition is an adventitious or anomalous communication between the cerebro-spinal sac and the nares, the mode of origin of which is readily comprehensible in the one instance and yet awaits demonstration in the other. The treatment, including the suggestion of lumbar puncture, is not very promising.

A SYSTEM OF MEDICINE. By Many Writers. Edited by THOMAS CLIFFORD ALLBUTT, M.A., M.D., LL.D., F.R.C.P., F.L.S., F.S.A.; Regius Professor of Physics in the University of Cambridge; Fellow of Gonville and Caius College; Hon. Fellow of the Royal College of Physicians of Ireland. Volume vi. New York: The Macmillan Company. 1899.

ABOUT a year ago we reviewed volume vi. of this excellent system of medicine, which was on diseases of the respiratory and circulatory systems, and now comes another volume vi. on diseases of the circulatory and nervous systems. Fortunately this confusion of volumes ceases with the title-page, the contents being different though of the same high order of excellence as those of the earlier volumes of the series. This volume contains the conclusion of diseases of the heart, articles on diseases of the blood and lymphatic vessels and of the muscles, and the beginning of diseases of the nervous system, including trophoneuroses, diseases of the peripheral nerves, and those of the spinal column and spinal meninges. Dr. William H. Welch is the only American writer in the volume, and to him, as the editor has previously complained, was due the delay of nearly a year in the appearance of the present volume. Evidently the writer wished to show himself untainted with the national vice of "hurry." His articles on thrombosis and embolism are disappointing. Among the articles on diseases of the circulation we have found the one on angina pectoris, by Sir R. Douglas Powell, and that on arterial degenerations (particularly arterio-sclerosis), by Dr. Frederick W. Mott, especially profitable. An excellent article is the one on diseases of the mediastinum and thymus gland, by Dr. Frederick T. Roberts. Another one deserving of special notice is that on the general pathology of the nervous system, by Dr. W. Bevan Lewis. It brings the reader of uncertain age, who has not kept pace with the wonderful progress of recent years in the minute anatomy and physiology of the nervous system, up to date, and places him in a position to study intelligently the succeeding article on diseases of the peripheral nerves, and more especially those on diseases of the brain and spinal cord which are presumably to appear in the next volume. A few pages are devoted very profitably to a consideration of the relations between general and ocular diseases, and of the information concerning the former which may be gained by an ophthalmoscopic examination.

PRACTICAL DIAGNOSIS: The Use of Symptoms in the Diagnosis of Disease. By HOBART AMORY HARE, M.D., B.Sc., Professor of Therapeutics in the Jefferson Medical College of Philadelphia; Physician to the Jefferson Medical College Hospital; Laureate of the Medical Society of London, of the Royal Academy of Medicine of Belgium; Corresponding Fellow of the Sociedad Español de la Higiene of Madrid; Member of the Association of American Physicians; Fellow of the College of Physicians of Philadelphia, etc.; Author of "A Textbook of Practical Therapeutics." Fourth edition, revised and enlarged. Philadelphia and New York: Lea Brothers & Co. 1899.

THIS new edition of Dr. Hare's excellent work appears in less than a year after the third. It differs but little from that, except that a few illustrations have been added and some slight alterations have been made in the text. The plan which the author has adopted in this work differs from that of most of the others of a like character, in that it takes the reader from the symptoms to the disease, and does not make him first guess at the disease and then see if the symptoms fit his hypothesis. This is, of course, the true principle of passing from the known to the unknown, and is the only

one by which true progress can be made in any science. The chapter on the information furnished by an examination of the blood is especially interesting, and is illustrated by several colored plates of much beauty as well as accuracy. The young practitioner can scarcely afford to be without some guide to a correct diagnosis in his early cases, and we know of no better general guide than the one before us.

## Society Reports.

### THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

*Stated Meeting, September 25, 1899.*

S. O. VANDER POEL, M.D., PRESIDENT.

**How Nature Utilizes the Iron Contained in the Blaud Pill.**—DR. WILLIAM HENRY PORTER read a paper with this title. He said that it had become generally recognized that both iron and manganese could not be absorbed from the healthy human intestine and carried into the body. It had been found that the iron taken into the system was largely derived from a substance called nucleo-albumin. It had been so called because first found in connection with the nuclei of cell life, and in association with albuminous material. Nucleo-albumin was especially abundant in green vegetables and in the legumina. Apparently it was a very complex substance resembling more especially the globulin series than the other proteid bodies. Nucleo-albumin formed in the cells of the vegetable kingdom was unquestionably the principal source of iron. When this substance was taken into the stomach in the form of food, it was acted upon by the digestive ferments and rendered less complex, being transformed so as to be capable of being taken up by the epithelial cells. By a process of oxidation reduction it became transformed into animal nucleo-albumin. While the nucleo-albumins were more abundant in the vegetable than in the animal kingdom they were more complex in the former, and those found in animal substances were more easily digested and assimilated. When the total quantity of nucleo-albumin in the food-stuffs was inadequate to meet the demands of the system, an anæmic condition of the animal economy must sooner or later follow. A too exclusive use of the animal foods would yield a like result. This was particularly noticeable in the infant fed entirely upon cow's milk: hence, the necessity for the addition of the vegetable class of food stuffs so soon as they can be utilized by the digestive system. To secure the highest grade of nutrition the animal and vegetable food stuffs must be carefully proportioned. The intake and output of iron in the system were comparatively small. Nucleo-albumin was the only source of the iron supplied to the system for the formation of hæmoglobin. In an ordinary mixed diet it was supplied far in excess of the daily needs of the system, but if this hæmoglobin-forming compound should be decomposed during its passage through the alimentary canal, it was easy to conceive that anæmia might follow.

Medical anæmia: Medical anæmia might be said to occur under three conditions, viz.: (1) When too little food was ingested, or the quantity of nucleo-albumins in the food was deficient; (2) when sulphur compounds were introduced into the alimentary canal, or digestive disturbances were present which led to the formation of an unduly large quantity of these sulphur compounds; and (3) when the chemico-physiological activity of the system was so disturbed that the nucleo-albumins could not be properly oxidized and utilized by the animal economy. The form of anæmia due to the last-mentioned factor was met with in the acute infectious diseases, in various toxæmias, and in many chronic affections. The sulphur compounds found in the alimentary canal in these cases drew the iron out of the nucleo-albumin, and formed an insoluble and unabsorbable sulphide of iron.

Preparations of iron: The so-called albuminates of iron were probably split up in the system into the chloride of iron and an albuminoid substance—indeed, there was evidence to show that all the vaunted medicinal preparations of iron were split up into the chloride of that metal before being utilized by the system. After the iron-bearing compound had been converted into a chloride the iron was quickly attacked by the sulphur compounds, with the result that an insoluble sulphide of iron was formed. It was this black sulphide of iron which, appearing in the stools, gave them the dark color observed when iron was being administered.

The Blaud pill: From the foregoing considerations it was evident that the old tincture of the chloride of iron was the most effective form of iron for therapeutic use except where the digestive system was very easily disturbed. When the latter condition existed it might be necessary to substitute the Blaud pill. This pill, as was well known, contained carbonate of iron and sulphate of soda when freshly made. If introduced into the stomach at this time the newly formed carbonate of iron was quite easily acted upon by the hydrochloric acid of the gastric juice, with the result that iron chloride was formed. This chloride quickly united with the sulphur compounds, and the nucleo-albumin was thus protected in its passage through the alimentary tract on its way to reach the liver cells—just as occurred when the tincture of the chloride of iron was administered. The use, therefore, of other preparations of iron only served to throw an additional tax upon the digestive system. This criticism applied to each and every other preparation of iron, whether official or not. Among the so-called vegetable compounds of iron was a proprietary preparation that had been made at his suggestion, and in accordance with the considerations just presented. It was nothing but a concentrated solution of nucleo-albumins derived from the vegetable kingdom, and hence was a food rather than a medicinal compound.

DR. WILLIAM L. STOWELL, in discussing the paper, said that he had gradually come to the use of three preparations of iron, the old tincture of the chloride, the Blaud pill, and the proprietary preparation referred to by the reader of the paper. He emphasized the importance of using only Blaud pills which had been freshly made.

**Some Important Points Regarding the Perfection of Asepsis.**—DR. CARL BECK read a paper with this title (see page 505).

**Strong Alcohol a Powerful Antiseptic.**—DR. H. J. GARRIGUES commended very highly the simple but very original and weighty advice, to discard the first knife as soon as the skin incision had been made, in order to avoid that very troublesome source of infection—the deeper layers of the skin. He said that it had been proved experimentally that by only moderately loud talking germs might be projected from the mouth a distance of several yards. One of the best ways of cleaning the skin was by the application of ninety-five-per-cent. alcohol. It was an old and tried remedy, and in some clinics was accorded a very high place as an antiseptic. It should be rubbed well into the skin and under the finger-nails by means of pieces of flannel.

DR. BECK, in closing, remarked that it had been demonstrated experimentally that fifty-per-cent. alcohol was a more powerful antiseptic than stronger alcohol.

## AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS.

*Proceedings of the Twelfth Annual Meeting, Held at Indianapolis, Indiana, September 19, 20, and 21, 1899.*

*First Day—Tuesday, September 19th—Morning Session.*

The association met in the Century Club Rooms of the Denison House, under the presidency of Dr. Edward J. Ill, of Newark, N. J. An address of welcome was delivered by Mayor Taggart, which was responded to by the president. After a brief executive session for the transaction of routine business, the reading of papers was begun.

**Three Rare Cases of Kidney Cysts.**—Dr. James F. Baldwin, of Columbus, Ohio, read this paper.

Case I.—Enormous hydronephrosis simulating ovarian cystoma. The tumor in this case filled the entire abdomen and entered the true pelvis, pushing the uterus to the left. The patient was unaware of the existence of a tumor, but thought that she had been getting stout for two years. There was no history whatever of any disturbance about the kidney. The enlargement was much more marked on the left side of the abdomen. At the operation the tumor was found to be hydronephrotic, of the right side, and with entire destruction of all kidney tissue. The blood-vessels had so far disappeared that the only pedicle was an enormously distended ureter resembling a piece of small intestine. The cyst, which was retro-colic, was enucleated without special difficulty, and recovery was uninterrupted.

Case II.—A large paranephric cyst containing about one and a half pints of straw-colored fluid resembling urine. The cyst wall was exceedingly thin, but was successfully enucleated, and the cavity closed with temporary drainage. Healing occurred by first intention.

Case III.—Hydronephrosis of a retro-rectal congenitally misplaced and sarcomatous kidney. This tumor filled the pelvis, pushing the uterus up and pressing so firmly upon the urethra as to necessitate the use of a catheter. The rectum was so pressed upon as to render defecation almost impossible. After separating the tissues the cyst was tapped through the vagina and about one quart of urinous fluid drawn off. The completion of the enucleation had to be made through the abdomen. The specimen proved to be a sarcomatous kidney congenitally misplaced in the pelvis. During the development of the disease hydronephrosis resulted, giving rise to the cyst which obstructed the pelvis. The patient recovered without difficulty and continued well at the time of the report.

Dr. Baldwin said that while hydronephrosis simulating ovarian cystoma was not excessively rare, paranephric cysts, of any considerable size at least, had been very seldom reported. The case of hydronephrosis of a pelvic kidney was, so far as the reporter could ascertain, after a somewhat extended correspondence, entirely unique.

Dr. James F. W. Ross, of Toronto, directed attention to a point in the diagnosis of cystic tumors of the kidney. It was this: Given a tumor that was unilocular by fluctuation, but looked like a multilocular tumor in consequence of the striæ, it was always a tumor of the kidney, and not of the ovary. As to the treatment of the ureter, if the end of it was tied with catgut, it could be left in the course of a nephrectomy. It was not necessary to follow the ureter down to the bladder.

Dr. Lewis S. McMurtry, of Louisville, agreed with Dr. Ross as to dealing with the ureter.

Dr. L. H. Dunning, of Indianapolis, mentioned a diagnostic point in cysts of the kidney, namely, the presence of the colon in front of the tumor. He had been able to demonstrate this in large sarcomatous tumors of the kidney. By pumping the colon full of air, the distended bowel could be seen running over the outer border or centre of the tumor.

Dr. J. Henry Carstens, of Detroit, stated that the point made by Dr. Dunning did not always obtain. He believed that when there was a loose kidney which flopped around, it might grow over the colon, and in some of the cases the colon was behind instead of in front of the tumor.

Dr. Joseph Eastman, of Indianapolis (by invitation), reported an interesting case of large pancreatic cyst, saying that it was very satisfactory to notice the ascent and descent of this tumor during inspiration and expiration, a thing not possible if the tumor had been post-peritoneal or connected with the kidney.

Dr. John M. Duff, of Pittsburg, narrated an instructive case in which a diagnosis of abscess of the spleen had been made, but a more careful subsequent examination revealed a kidney tumor, which was removed by operation.

Dr. Dunning asked as to the reliability of the Harris instrument for examining the urine of the two kidneys, to which Dr. Baldwin replied that it was very satisfactory. He had used it several times in women, and considered that it could be used more quickly and with less trouble than ureteral catheterization.

**Ectopic Gestation; Shall the Case be Operated upon At or Near Full Term, the Child being Alive?**—Dr. L. H. Dunning, of Indianapolis, read this paper. He reported the history of a case of ectopic gestation of eight months' duration, and which was operated upon five weeks after the death of the fœtus. The proper treatment of ectopic pregnancy after the sixth month, when the child was still living, was still under discussion. His paper was written for the purpose of considering one phase only of the subject, namely, Shall operative intervention be instituted during the period of viability of the child, or shall we await the death of the child, and the cessation of the active circulation of the placenta, and then operate? The settlement of this question, he said, must hinge upon the relative mortality to the mother of the different procedures. The ectopic infant was of such low vitality and so frequently deformed that if to rescue it greatly jeopardized the life of the mother, then ethically one must withhold the hand and permit the child to die that the greater life might be saved. Such had been the sentiments of the writer for many years. He had had three cases of ectopic gestation at or near full term. In the first, the operation was done during spurious labor at full term. Although fœtal movements were detected one hour before operation, the child never breathed after removal by abdominal incision. The mother died the eighth day after the operation, of hemorrhage resulting from the removal of the placenta, which was left at the time of the initial operation. The placenta was removed thus early in consequence of impending death from septicæmia. The other two cases were briefly narrated. A statistical table accompanied the paper. His only endeavor was to strive to arrive at a correct answer of the question, "Is it safer for the mother to be operated upon in a case of ectopic gestation during the viability of the fœtus?" He believed that the statistics collected and compiled by him were so nearly complete and correct that the answer could now be given unqualifiedly in the affirmative.

Dr. J. Henry Carstens agreed with the essayist that the proper way, other things being equal, was to operate at once when the child was living and viable. The placenta was not always attached to the broad ligament. Often rupture took place, and the placenta was attached to the intestine, the colon, the rectum, or the sigmoid, and in cases of that kind it was utterly impossible to remove the placenta when an operation

was undertaken when the child was alive. He had seen such operations performed by other surgeons, but the patients invariably died of hemorrhage.

Dr. Lewis S. McMurtry narrated a case in which the fœtus had gone to full term, was dead, and some weeks after a spurious labor, when there were beginning septic symptoms, he operated. No fœtal movements had been observed for nearly three weeks. The placenta was very large; there was no sign of any atrophic changes in it in consequence of the death of the fœtus; it was spread out over one side of the uterus, over the colon and ileum, and there was a profuse hemorrhage attending the enucleation of the placenta. When the placenta was disposed toward the broad ligament and uterus, Dr. McMurtry believed that there was a good opportunity for its complete enucleation.

Dr. X. O. Werder, of Pittsburg, said he had reported a case in which he had done a cœliotomy for ectopic gestation at full term, or within two weeks of full term. He succeeded in enucleating the placenta and removing at least two-thirds of the sac. The rest of the sac was adherent to the intestines, and it was found advisable to stitch it to the abdominal wall. Hemorrhage during the removal of the placenta was very profuse, but was controlled promptly by clamping the uterine and ovarian arteries. The woman recovered, and the child lived four days.

Dr. Joseph Eastman fully concurred in the conclusions of the essayist, and narrated an interesting case of ectopic gestation that had come under his observation ten years ago.

Dr. John M. Duff was of the firm belief that in every case of extra-uterine pregnancy, when the diagnosis was made, arrangements should be perfected for an operation as soon as possible.

The paper was further discussed by Drs. Gilliam, Ricketts, and Ross, all of whom, with slight differences of opinion, agreed with the essayist.

Dr. Lewis S. McMurtry, of Louisville, presented some observations, chiefly clinical, upon the temperature after intraperitoneal operations.

**What Shall We Do with the Post-Operative Hemorrhage of Cœliotomy?**—This paper was read by Dr. Tod Gilliam, of Columbus, Ohio. Cases of post-operative hemorrhage were cited. The author stated that he had very little to offer in the way of suggestion. As a burnt child dreaded the fire, so his most painful experience in tragic cases cited by him had imbued him with a wholesome dread of delayed interference after cœliotomy. He had on several occasions opened the abdominal incision down to the peritoneum on account of hemorrhage from the walls, without untoward results. This class of cases could usually be easily distinguished from intraperitoneal bleeding by the puffed and discolored appearance of the tissues along the line of incision. If he was satisfied that a large vessel had let go, as indicated by the rapid development of symptoms indicative of hemorrhage, he would open the abdomen with the utmost celerity. As to the vital question, when to interfere surgically and when to refrain, the paper ended where it began—in an interrogation point.

Dr. Charles A. L. Reed, of Cincinnati, stated that when he observed symptoms unmistakably indicative of internal hemorrhage, he wanted to get at the bleeding point as quickly as possible. He cited cases in which he had dealt with post-operative hemorrhage following cœliotomy.

Dr. H. W. Longyear, of Detroit, stated that if he knew a vessel was bleeding, he considered it his duty to cut down and search for it, no matter what the condition of the patient was. In a case of ruptured tubal pregnancy, in which internal hemorrhage was taking place, it was the duty of the surgeon to reopen the abdomen and do the best under the circumstances.

Dr. Rufus B. Hall, of Cincinnati, thought that hemorrhage or shock could be determined largely by the operator himself. When a patient was put to bed after an operation the surgeon was well aware as to whether there was great danger of secondary hemorrhage or not. If the operation had been a complicated one and a condition was left which added to the risk of hemorrhage, this aided the surgeon materially in determining whether or not the patient was bleeding or suffering from shock. He would not hesitate to remove a stitch, after the abdomen had been closed without drainage, and he believed without very extensive exploration he could determine readily and certainly whether hemorrhage was going on or not.

Dr. Lewis S. McMurtry said that in the early days, before operative technique was developed and improved as it was now, and the drainage tube was more universally used, it was common twenty-four or forty-eight hours after an operation to see great quantities of blood pumped out of the drainage-tube. Hæmostasis was not so thorough then as it was now. To-day the small vessels were ligated carefully. He had pursued the course of securing the ends of vessels with fine ligatures, which gave additional security.

Dr. J. Henry Carstens dwelt upon the differential diagnosis between hemorrhage and shock.

Dr. James F. W. Ross said that in cases of thick pus tubes with a very œdematous pedicle the surgeon was liable to have such a hemorrhage, particularly from the œdematous pedicle and rotten condition of the tissues afterward. He would not hesitate to remove a stitch and search for the bleeding vessel.

Dr. L. H. Dunning called attention to a valuable diagnostic sign in differentiating between shock and hemorrhage. He had seen shock occur in twelve, twenty-four, and thirty-six hours after operations. He had also seen patients recover from shock who could not have recovered from hemorrhage. The differential diagnostic sign was that of irregular capillary circulation or congestions here and there. He recalled three or four cases in which he had spent hours at the bedsides of patients, hesitating between shock and hemorrhage, but on the appearance of localized spots, as a purple ear or purple lip, or a spot upon the face, he decided it was shock.

Dr. X. O. Werder stated that it was his rule, as soon as he suspected a hemorrhage after an operation, to take out a stitch and insert his finger for the purpose of determining the existence of hemorrhage, and if his suspicions were confirmed he reopened the abdominal wound and tied the bleeding vessel without anæsthetizing the patient.

Dr. Edwin Ricketts, of Cincinnati, said that whenever ligatures were used, there was one procedure to which he desired to direct attention, one always resorted to by Bantock—and that was, crushing the tisssues for half or one-quarter of a minute with the heavy jaw clamp, and after the removal of the clamp applying the ligature. Hemorrhage was controlled in this way.

Dr. William H. Humiston, of Cleveland, thought that if each vessel was caught separately and tied with fine catgut or silk, reinforced by seizing the ovarian artery as it came off the pelvic wall, and inserting one stitch in it and one near the corner of the uterus, hemorrhage need not take place. He thought it was unnecessary to crush the tissues after the method mentioned by Dr. Ricketts.

---

*First Day—Afternoon Session.*

**Coccygeal Dermoid Fistulæ.**—Dr. Robert T. Morris, of New York, made some remarks on this subject, saying that coccygeal dermoid fistulæ was a theme that had not received very much attention, as he had found little reference to it in medical literature. Occasion-

ally some one had reported the findings of a dermoid cyst in the coccygeal region, but without making comments on the way in which such cysts were likely to have been formed. He had seen reference to cysts only, but on studying the subject he had found that surgeons were much more apt to find fistulæ than cysts. They were more apt to find depressions than fistulæ. In the region of the coccyx not infrequently funnel-shaped depressions of the skin were found. Fistulæ were less frequent, extending to a depth of from half an inch to four inches in his deepest case; and still less frequently wholly encapsulated cysts were observed. These fistulæ and cysts contained straight hairs of the lanugo type mostly, although he had seen some nearly three inches in length, straight, in a mass, and welded together by sebaceous material. The sebaceous material escaped in large quantities from the fistulæ; it remained encapsulated in the cysts and in the funnel-shaped depressions; it frequently dried upon the surface and came away in the form of scales mixed with epidermis. These funnel-shaped depressions or fistulæ, or cysts of the coccygeal region, evidently represented an embryonal defect. There was a possibility that the tail of the embryo in undergoing involution left a portion of the skin highly endowed with embryonal latent cells, and that the skin, developing more perfectly in the connective tissues about it, encapsuled, in part or in whole, this absorbing or involuting embryonal tail, so that in a coccygeal fistulæ we had an inverted tail. He had had four cases of coccygeal fistulæ come under observation up to the present time which contained masses of hair. In their removal the surgeon must remove the entire cyst wall or fistula wall, because it consisted so largely of embryonal tissue that recurrence took place promptly unless this was done. The method of treatment with nitrate of silver and with caustics resulted only in temporary destruction of the inner layer, just as when the surgeon tried to destroy branchial cysts or branchial fistulæ. The author cited a case in point and exhibited microscopic slides.

**House-to-House Operating.**—Dr. Edwin Ricketts, of Cincinnati, Ohio, read this paper. The skilled abdominal and gynæcological surgeon of to-day was a product of surgical evolution, to which no man ever gave such an impetus as the great and lamented Mr. Lawson Tait. From him we had learned that the best results depended upon simplicity, thoroughness, rapidity, and rigid cleanliness, and that his best work was done in house-to-house operating. The advantages were many. Briefly, they were: (1) The greater ability of the general practitioner to attend to the after-treatment, assisted by a competent nurse, the telegraph, and telephone. (2) The absence of the mental dread of the patient to go into an institution, and the risk therein entailed, a condition by no means to be underestimated. (3) Iron bedsteads and improved household furniture were rapidly finding their way into country homes. (4) God's pure air, and, undeniably, less liability to infection. With reference to the use of antiseptics, it was necessary to mention but one fact, a quotation from Richelot, that "the elimination of all micro-organisms during the operation by antiseptics had not been attained." Consequently their use was to be condemned, and in their stead surgeons should rely upon hot water, a dry wound, and rapid operating, which meant a shorter time under the anæsthetic—a very important consideration.

A spirited discussion followed the reading of this paper, the majority of the speakers taking issue with the essayist except in emergency cases.

**Primary Sclerosis of the Ovary.**—This paper was read by Dr. William H. Humiston, of Cleveland, Ohio. The author said that there were two distinct pathological conditions now classed as sclerosis of the ovaries, and universally believed to be due to inflammatory changes. There were a primary or non-inflammatory sclerosis and a secondary or inflammatory fibrosis. These forms could be recognized both clinically and by microscopical examination. In the secondary degenerations was found (in a section taken from some portion of the ovary) a small round-celled infiltration, or the connective-tissue elements in some of their various stages of development. Also, however advanced the stage of fibrosis might be, the numerical relation of nuclear to cellular elements in this variety was always greater than in the primary form. Thirdly, the microscopical appearances of the vascular system were also different. In the inflammatory group there was primarily a dilatation of the vessels with secondary contractions of their greatly thickened walls and a lessening of their lumen. In the primary group there was usually no thickening of the vessel walls; there was never any dilatation, and contraction occurred so early that one immediately noted the poor blood supply, particularly to the periphery of the organ. In those cases of arterio-sclerosis of the vessels, within the broad ligament was usually found the condition extending to the vessels entering the ovary, not otherwise. Lastly, in the primary group the epithelial cells of the ovarian stroma were diminished in number and usually in size. In some sections they were hard to distinguish from the connective-tissue elements, and appeared to undergo a process of reversion. These several microscopic differences were constant and decidedly marked. Summarizing the history and points for differential diagnosis, he stated that the condition was non-inflammatory and without a history of infection and of signs of peritonitis. It occurred in early life, from puberty to the age of thirty, with dysmenorrhœa often since the first catamenia. Amenorrhœa or delayed menstrual flow and intermenstrual dysmenorrhœic pain, described by every patient as being alike in character and severity with the pains experienced during each catamenia, were constant. This latter symptom differentiated the origin of the dysmenorrhœa, making it clearly ovarian rather than uterine in its causation, and in itself was of chief importance clinically. In not a few cases there was evidence of a granular and contracted kidney. In a large percentage of cases a marked sclerosis of the walls of some one or more arteries could be demonstrated. The ovaries, one or both, were always within reach of the examining finger, and their condition as to size, shape and consistency could be determined. Neurasthenia developed early in these cases, but was often superseded by one of the various neuroses.

**Intestinal Adhesions in Suppurative Pelvic Disease; Their Significance after Vaginal Hystero-Salpingo-Oöphorectomy.**—This paper was read by Dr. F. Blume, of Pittsburg, Pa. The time had passed when a surgeon could say without jeopardizing his reputation that he operated exclusively by the abdominal or the vaginal route. He had seen many women who, after abdominal section for pelvic suppuration, performed in this country and abroad, were invalids, and he had done secondary operations upon a number of them. He had not, however, been called upon to treat a woman upon whom vaginal hysterectomy was performed by another surgeon, nor had any of his patients required or sought treatment at the hands of other operators. His experience was in accordance with the observations of other writers, and justified the assertion that the results of vaginal hystero-salpingo-oöphorectomy in suppurative pelvic disease were excellent, notwithstanding the suprapelvic complications, and there was no class of cases which, as a whole, gave more satisfaction. The author's first case of intestinal obstruction occurred in a series of

forty-two vaginal hysterectomies, and was reported last year. Since then he had done nine vaginal hystero-salpingo-oöphorectomies for pelvic suppuration, and had had another case of ileus, the history of which was detailed.

*First Day—Evening Session.*

This session was devoted to the exhibition of pathological specimens, of which the operators gave brief histories, and short discussions followed.

*Second Day—Wednesday, September 20th—Morning Session.*

**Shall We Abandon Ventro-Fixation of the Uterus?**—This paper was read by Dr. Walter B. Dorsett, of St. Louis, Mo. The question asked implied that some doubt existed as to the propriety of the operation of fixing or suspending the uterus to the abdominal wall. The object of the paper was not to discuss the different methods of correction of displacements of the uterus, nor the results or accidents that were liable to and occasionally did follow them; but it was for the purpose of drawing attention to one method which, on account of the unfortunate results that had now and then followed it, had been, to a certain extent, abandoned by some operators. He referred to ventro-fixation. By ventro-fixation, as practised by himself, he did not mean ventro-suspension as originated and practised by Kelly and others. His experience had not been followed by the results reported by others who had worked along the same lines. *Per contra*, it had been highly satisfactory. Prior to four weeks ago he had made thirty-eight ventro-fixations, and to the present time had had no failures in keeping the uterus in its proper place. Four of the patients had borne children without any of the usual troubles reported in pregnancy or during the delivery of the child, and none had had entanglements of the bowels or omentum. Of these operations, eight were done to correct different degrees of prolapsus, and the remainder were for retroflexions and retroversions. Fifteen of the latter were complicated with ruptures of the perineum and cervix, which were previously repaired by himself or others before the final operation was done. Sixteen patients were married women of the child-bearing age, *i.e.*, between the ages of twenty-three and thirty-nine years. Twelve were cases of marked disease of the adnexa; five of double pyosalpinx and abscess of one or both ovaries; and two of disease of one tube and one ovary. Six were marked neurasthenic women in whom there was a pronounced relaxed condition of the entire muscular system, predisposing the individual toward retrodeviation.

Dr. Dorsett then described at length the technique of the operation, his remarks being illustrated by blackboard sketches and numerous diagrams.

**Two Cases of Dystocia following Ventro-Fixation, One Requiring Cæsarean Section.** Dr. X. O. Werder, of Pittsburg, read this paper, in which he reported five cases of firm ventro-fixation followed by delivery at term. In two cases dystocia followed this operation done for complete prolapse of the uterus with inversion of the vagina. One case terminated spontaneously, the other required Cæsarean section. The former case had been operated upon by himself, the latter by another surgeon. In both cases a series of operations were done at one sitting, including curettage, amputation of the cervix, anterior colporrhaphy, ventro-fixation, and perineorrhaphy. In his own case, very firm fixation of the fundus and posterior wall of the uterus to the abdominal wall was made in order to be sure of relieving the prolapse. In the other case infection was said to have been the cause of broad attachment and firm fixation. He excluded from discussion other procedures intended to hold the uterus in anterior position, and defined the limits of ventro-fixation as follows: It was the operation of preference in cases of complete prolapse of the pelvic organs, and in cases in which a very large, heavy uterus, due to chronic metritis, was habitually retroverted or retroflexed, and caused pronounced symptoms. In these cases he thought less rigid fixation was ineffective. The fixation should be between the anterior uterine wall (not the fundus or posterior wall) and the angle of the wound. He attributed the serious after-results to errors in technique rather than to the procedure itself.

Dr. H. W. Longyear, of Detroit, Michigan, read a paper in which he described a simple, effective, and æsthetic operation for shortening the round ligaments.

**Memorial Address.**—This was delivered by Dr. Charles A. L. Reed, of Cincinnati, Ohio, on Lawson Tait, the great Scotch surgeon, of Birmingham, England, who died at Llandudno, Wales, June 13, 1899, and who was an honorary member of the association. Dr. Reed reviewed his life, noting that he did his first ovariotomy July 29, 1868, in the earlier months of his twenty-fourth year, and five others before 1870, when he removed to Birmingham. Mr. Tait shaped his practice according to his convictions. He modified his technique in the direction of simplicity. One accessory after another was laid aside, until a knife, scissors, needles and thread, a few hæmostatic forceps, some sponges, and tap water were the essential constituents of his armamentarium. This eminent surgeon characterized the great parade of instruments in the operating-room of a distinguished Parisian surgeon as suggesting an intention to fight over again the battle of Waterloo. The year 1879 fairly bristled with new achievements. He did his first cholecystotomy, a procedure in which he had been anticipated eleven years by Dr. Bobbs, of Indianapolis. Dr. Reed gave in detail the record of the achievements of this resourceful man, and of the many activities other than surgery in which he engaged.

**President's Address.**—This was delivered by Dr. Edward J. Ill, of Newark, N. J., who selected for his subject "The Rights of the Unborn; the Prevention of Conception." The rights of the unborn would be more respected if it could secure for itself competent legal authority to represent it before a court of law. He held that the induction of abortion was performed too frequently; that the law and custom of consultation left a wide field for opinion, judgment, and professional courtesy. Too frequently the practitioner's sympathy ran away with his reason. The frequent deaths of the unborn as caused by the regular profession legitimately must ever remain a sign of weakness and impotence of an otherwise noble and humane profession. The indication for such an operation must greatly change with the advances of therapeutics. Before long, he thought, we would be told that the life of the fœtus must not be taxed less than that of the mother. When that became an axiom, our resources would increase to an astonishing extent. Cæsarean section was now commonly performed with the greatest likelihood of saving mother and child, and with much less risk to the mother than was formerly incurred by induced abortion. He discussed pregnancy complicated with myomata, carcinoma of the cervix, hyperemesis, etc.

**Retroperitoneal Tumors, with Report of a Case and Presentation of Specimen.**—This paper was read by Dr. Rufus B. Hall, of Cincinnati, Ohio. He said that the retroperitoneal tumors that are operable are rare. The author's experience in dealing with them, so far as the removal of the tumor was concerned, had been limited. All retroperitoneal tumors were difficult to remove, and the operation was attended with

a high mortality. They were often malignant. The specimen he presented was probably a fibroid tumor of the uterus. When the tumor was removed eighteen months ago, it was so soft and so unlike a fibroid tumor in appearance and consistency, that he doubted this very much. The attachment of the uterus was so indistinct that one would doubt that it had its origin from that organ. The tumor was wholly post-peritoneal; it occupied the patient's right side, almost wholly filled the pelvic cavity, and projected well into the abdomen. Dr. Hall then detailed the case. The record showed that it was not always necessary to abandon an operation when the tumor was found to be retroperitoneal. In some cases these tumors could be removed without great difficulty, and the patient would make a complete and permanent recovery. It might not always be possible to determine which case could be safely operated upon until after the abdomen was opened. If the tumor was somewhat movable and the peritoneum not firmly agglutinated to the tumor mass, these tumors could be removed.

**Rupture of the Puerperal Uterus, with Cases.**—Dr. James F. W. Ross, of Toronto, read a paper with this title. He said it was well known that rupture of the uterus might occur before or during labor. To diagnosticate a rupture of the uterus before labor was extremely difficult. It was a subject about which very little was known. The cases under discussion were not those before labor, but those occurring at the time of labor. Every practitioner should be familiar with the symptoms of this condition, so as to be able to recognize it at as early a date as possible after its occurrence. He then mentioned the different causes of rupture of the uterus, that are well known. The question as to whether rupture of the uterus occurred more frequently in the first or in subsequent labors was still one that had not been settled. Some authorities claimed that rupture of the uterus was more frequently met with in primiparous than in multiparous cases; by others it was thought to be more frequently met with in multiparous than in primiparous cases. Some stated that rupture of the uterus might take place before the membranes had been ruptured. He considered that the duration of labor had a great deal to do with the production of rupture of the uterus, as the organ seemed more prone to tear after its structure had become impaired by continual and prolonged contraction. The fundus was less frequently ruptured than the body, and the body less frequently ruptured than the cervix. The posterior wall of the lower segment seemed to be the commonest site of rupture, and the tear was generally found to run toward the left. These tears usually extended over a distance of three or more inches. Cases of rupture of the uterus should be divided into four groups: first, those that were beyond hope from the first, that had the usual classical symptoms of rapid pulse, dyspnœa, precordial uneasiness, nausea, vomiting, and cold perspiration. Second, those cases that had, owing to delay, passed beyond the operable stage and in which the patient had become ill with commencing septicæmia and peritonitis, the peritonitis and septicæmia drawing attention to the case, and this extra attention revealing the fact that rupture of the uterus had been present without giving rise to early symptoms to indicate its existence. Third, a class of cases in which rupture was not immediately fatal, in which it was early recognized, and in which the patient was in good condition for operative interference. Fourth, a class of cases that might occur in which rupture was never recognized, but in which septic symptoms developed without any evident reason. In a case in which a very rapid pulse followed a fairly severe labor, and peritonitis set in, rupture of the uterus must be considered when endeavoring to discover the cause of the abnormal course of the puerperium. Intraperitoneal hemorrhage could be diagnosticated by percussion in the loins. The writer had diagnosticated it in this way on several occasions. The percussion sound might change as a consequence of the changed position of the clot, and when it did change it did so slowly. Since reading a paper before the Buffalo Academy of Medicine in January, 1898, he had met with two cases of rupture of the uterus. These were related in detail. One case occurred at full term, and the other during the fourth month, the latter having been produced by an attempt to empty the uterus. In each case drainage of the peritoneal cavity through the rupture and frequent irrigation were adopted. Each patient recovered after a long-continued illness. The rupture was not recognized in either case in time for interference by cœliotomy. In summing up the treatment of these cases, he considered that it was necessary to treat them according to the class to which they belonged. In the first class the patient was practically moribund before the physician in charge could call counsel. In the second class of cases, in which there were no symptoms to indicate that rupture of the uterus had occurred, the treatment must vary from that carried out in class three. The treatment in the second class was that indicated in the cases reported, namely, thorough drainage and thorough cleansing from below. In the third class of cases in which rupture was recognized, in which the patient was not moribund from shock and hemorrhage, there could be but one line of procedure to carry out, viz., cœliotomy, thorough inspection of the part, removal of blood clot from among the intestines, thorough stoppage of hemorrhage from the wound either by approximating sutures or gauze packing, and the establishment of thorough vaginal or abdominal drainage, or both. In the opinion of the essayist, suturing the rent was scarcely called for, and by this procedure the operation was unnecessarily prolonged, and the length of time consumed by such an operation was of importance. Any one who had had experience with this tragedy of the lying-in ward must have noticed that the edges were so bruised as scarcely to hold a suture. To pare them off meant increased hemorrhage and increased delay. He preferred packing with gauze, and was satisfied that the uterus afterward became perfectly normal. Hysterectomy under such circumstances must prolong the operation, increase the shock, and unsex the patient. In the treatment of the fourth class of cases, or those unrecognized, the question of improvement in means of diagnosis must be considered. How could it be discovered when it presented no symptoms? When inflammation and septicæmia were present, it was too late to make a diagnosis. He had not the fear of exploration of the interior of the uterus ordinarily taught by text-books. He did not consider this a sort of sacred chamber into which the finger of the accoucheur should seldom be put. He believed that in all cases of septicæmia following labor in which there was a greatly increased pulse without any apparent reason, the interior of the uterus should be thoroughly explored with the finger to ascertain the absence or presence of a rent.

**Wounds of the Liver and Biliary Tract.**—This was the title of a paper by Dr. W. E. B. Davis, of Birmingham, Ala. Penetrating wounds of the liver were not common. The surgeon might inflict such injuries in the treatment of hydatid cysts and abscesses of the liver. Severe wounds usually proved fatal. There was often injury to the biliary canals of the liver, and the extravasation of bile contributed to the fatal issue. He reported three cases illustrating injuries produced by the surgeon. The first case was that of a man, aged sixty years, in whom there was only one-half ounce of pus found in the right lobe of

the liver, but in searching for this small cavity a wound of very considerable depth and great size—perhaps two inches in length—was inflicted. There was very profuse hemorrhage, which was controlled by iodoform-gauze packing. Great quantities of bile were discharged for three weeks. The patient made an excellent recovery. He attributed this result not only to the drainage of pus, but to the opening up of some of the biliary canals which resulted in the emptying of the liver. The second case was that of a woman, thirty years of age, in whom there were attacks of pain, fever, and jaundice from a movable stone in the common duct; the liver became very much enlarged, and during an attack of peritonitis an incision was made and the right lobe of the liver freely opened and packed with gauze. There was no pus in this case. The patient rapidly recovered. The liver returned to its normal size and the stone was passed some months after, when the patient was being prepared for a radical operation. He also reported the case of a woman, sixty years of age, whose symptoms indicated obstruction of the common duct. The liver extended almost to the umbilicus. No nodules were to be made out on the surface. There being no obstruction in the common duct, it was decided that the obstruction was in the hepatic duct or its branches. A free incision was made into the right lobe of the liver with the hope of opening some of the biliary canals and thus relieving cholæmia. Death occurred a few days after from exhaustion. The patient was almost in a dying condition at the time of the operation. A large malignant nodule was found at the autopsy in the transverse fissure, which completely obstructed the branches of the hepatic duct. Dr. Davis said that wounds of the biliary tract beyond the liver produced death, not so much from the sudden escape of bile as from the continuous pouring of fresh bile into the peritoneal cavity. Gallons of fluid would not cause death if there were protective adhesions. He narrated a case of gunshot wound illustrating this point, the patient being cured by repeated tappings. Large quantities of bile had been removed at the first operation. He also detailed experiments on animals in which the adhesions had given way after two weeks, and death resulted from peritonitis. He said that rupture of the liver might be limited to the upper or lower surfaces, or that the organs might be completely torn through, the parts being held together by the veins. In four cases of operations on dogs he had removed more than one-third of the liver, all of them dying. In one case in which he removed the extreme left lobe of the liver the animal made a complete recovery. Six cases of operations on animals were detailed, illustrating the fact that small quantities of bile could be injected into the peritoneal cavity without harm. In one case he injected as much as five drachms of bile. He mentioned twenty-three cases of operations on dogs to demonstrate the effect of bile on the peritoneal cavity. In those cases in which only a small escape of bile took place the animals recovered; in those in which there was considerable extravasation, the animals died in from one to three days. The omentum and abdominal viscera in these cases were highly bile-stained, but there was not the redness of the intestines that was observed in septic peritonitis. The treatment of these cases consisted in promptly opening the abdomen, controlling the bleeding by gauze packing, and drainage. The essayist reported a large number of cases in which he had produced wounds of the gall bladder and ducts of dogs which had been successfully dealt with in this way. The opening in the bladder or duct closed as quickly as the fistula of a cholecystostomy.

Dr. William H. Myers, of Fort Wayne, Ind., followed with a paper in which he dealt with the past and present surgery of the gall bladder and bile ducts.

*Third Day—Thursday, September 21st—Morning Session.*

**Hemorrhage and the Menopause.**—Dr. John Milton Duff, of Pittsburg, contributed this paper. He did not believe that hemorrhage was a necessary concomitant of the menopause. When it did occur other than as a metrorrhagia in the true sense of that term, it was in ninety-five per cent. of the cases significant of a pathological condition. During the past three years he had interrogated, or had had others do it for him, four hundred and eighty-two healthy women over fifty-two years of age. Of these only thirty-nine gave a history of what could be termed a hemorrhage during the menopause, and of this number only five gave a history of persistent hemorrhage. In one hundred and eighty-seven tabulated cases, between forty-three and fifty years of age, suffering from uterine hemorrhage, nineteen were due to pregnancy, forty-eight to malignant disease, fifty-three to fibroids or uterine cysts, ten to diseased endometria, twenty-six to diseased appendages, while in thirty-one no positive diagnosis was made. In view of such statistics the author failed to see how any physician could argue, as he had heard them do, that hemorrhage during the menopause was not as a rule significant of disease. Finally, "all persistent hemorrhages during the menopause should be regarded with suspicion."

**Report of Four Additional Cases of Uterine Fibroids Complicating Pregnancy.**—Dr. M. Rosenwasser, of Cleveland, Ohio, read this paper. To the four cases reported in the paper the author added abstracts of three previously published in the Transactions of the association. The report formed the basis of a discussion of the subject under the following headings:

I. Before delivery: (*a*) In the interest of mother and child—(1) Non-intervention; (2) myomectomy; (3) Porro operation; (4) vaginal Cæsarean section. (*b*) In the interest of the mother—(1) Induction of abortion; (2) hysterectomy.

II. After delivery: (*a*) Non-intervention. (*b*) Hysterectomy, indicated by recurrent hemorrhage, and septic infection.

Non-intervention was recommended whenever, on account of its location, the tumor did not interfere with delivery, or when its moderate growth would admit of delay until viability of the child. Myomectomy for pedunculated fibroids was a safe procedure; but the enucleation of fibroids before viability risked the life of the child, as abortions were frequent. After viability it was indicated when it was desirable and possible to preserve the uterus, or during labor when myoma of the cervix obstructed the pelvis and could not be dislodged. The Porro operation was the safest procedure after viability of the child, or at term if the tumor obstructed delivery and if the uterus must be sacrificed. Vaginal Cæsarean section, as proposed by Dührssen, had not yet been tried. Induction of abortion was considered more dangerous and less readily controllable than hysterectomy. Distress from abdominal distention or pressure, interference with vital functions, great and constant anxiety might require hysterectomy as an emergency operation. When the tumor was located in the lower segment of the uterus, or in the anterior lip of the cervix, or in the broad ligament, and encroached on the pelvic space so as to constitute a barrier to delivery, the patient was entitled to her choice of time of intervention, whether before or after viability of the child. After safe delivery, only distinct indications warranted any intervention. Post-partum hemorrhage and sepsis should be managed the same as though no tumor was present. Hysterectomy became necessary during the puerperium when the hemorrhage could not be permanently

checked, or before infection or sloughing of the myomatous uterus or the retention of the secundines had led to general acute septicæmia.

**Technique of Abdominal Hysterectomy.**—Dr. J. Henry Carstens, of Detroit, contributed this paper. The following is a *résumé* of his contribution: The usual careful aseptic preparations were carried out. The patient was placed in the Trendelenburg position. After freeing the adhesions, the uterus and growth were pulled out of the abdominal cavity with the aid of a corkscrew. The intestines were kept in place by abdominal towels. Clamps were placed on each broad ligament outside of the ovary. The broad ligament was cut one-quarter of an inch from the clamps down as far as the latter extended. A cut was made across the uterus anteriorly from the point of one clamp to the other through the peritoneum, and the bladder was separated from the uterus. Another pair of clamps were now placed on the broad ligament down to the cervix, and the remainder of the broad ligament was cut to the point of the clamps. The slight attachment to the vagina and anteriorly was now easily separated, and the growth and uterus were removed. It would be noted that there were four clamps, two containing each ovarian artery and two containing the uterine arteries. Each artery was now separately ligated with dry sterilized catgut. If the arteries of the round ligament were large, as they sometimes were, they also required a ligature. The clamps were removed and the stumps and raw surfaces carefully covered with peritoneum by a running suture of dry sterilized catgut. If the cervix was removed, a small opening was left for a temporary gauze drain. If the cervix was left in, no drainage was used except in septic cases, when a puncture in the posterior cul-de-sac was made use of for a rubber drain. Dr. Carstens concluded: First, in abdominal surgery, the broad ligament should be clamped and the growth and uterus removed. Second, the four blood-vessels should be ligated separately. Third, all raw surfaces should be carefully covered with peritoneum. Fourth, in cases without tears and healthy mucous membrane the cervix was to be left in. Fifth, in any diseased condition of the cervix and malignant growth total hysterectomy must be performed.

**The Treatment of Inertia and Subinvolution.**—Dr. Charles Stover, of Amsterdam, N. Y., contributed this paper. He said that the practice of discharging puerperal cases after the third day, with the direction that if anything goes wrong the doctor is to be recalled, deprived the lying-in woman of an opportunity for the detection of subinvolution. The stasis of the circulation and absence of muscular contraction led to metritis, endometritis, retroflexion, and prolapsus. Muscular contraction might be secured by the physician at all stages of labor to overcome inertia and during convalescence to prevent subinvolution. In the treatment of inertia during the first stage of labor, ergot was to be condemned, and rest secured by sleep. In the second stage, instrumental delivery would usually be indicated, but the slowly interrupted faradic electrical current was useful, selecting the primary current when the secondary might be painful. Strychnine was to be given in doses of gr. $\frac{1}{30}$ or $\frac{1}{60}$, repeated in two hours if necessary. Ergot was not advised, save in exceptional cases, and then in doses of ♏ v. every fifteen or thirty minutes. In the third stage, when post-partum hemorrhage might have complicated the situation, after the coagula had been emptied out and the secundines removed beyond doubt, the faradic current was of great value. It might be applied with one pole over the abdomen, and one at the lumbar spine. This was usually sufficient, but the intrauterine bipolar application might accentuate its efficiency. The telescopic electrode invited sepsis. Ergot should be given hypodermatically. Manual compression and massage should not cease for an instant. The treatment of subinvolution presupposed the exclusion of endometritis, fibroids, retained secundines, or any pathological state, the condition being distinguished by stasis and muscular inaction. The interrupted faradic or galvanic current was to be used daily. Hot-water douches, as outlined by Emmet, were of value. Boroglyceride tampons, daily or every other day, were likewise helpful by depleting the tissues. Ergot was still of use, particularly in sthenic and rheumatic subjects, when combined with the citrate of potassium as used by Lawson Tait, in doses of ʒ ss.–i. in a half-pint of water four times daily an hour before meals and at bedtime. Indian hemp might at times go with the ergot. Saline cathartics and an occasional cholagogue were often useful to unload the pelvic veins and quicken the portal circulation. Iron was used in anæmic cases very early, with quinine, cinchona, and gentian as adjuvants. Lactation was considered to be a physiological and complementary function in promoting involution.

**Choice of Method for Total Hysterectomy, and Some Points of Technique.**—A paper with this title was contributed by Dr. B. Sherwood-Dunn of Boston, in which he compared the abdominal operations by Richelot, Le Bec, Doyen, and Martin with the American method, much to the favor of the last-named, and emphasized the advantages of the preservation of the cervix by giving five reasons in its favor. These reasons were: (1) Prolonging of the operation because of hemorrhage from the lateral and posterior vaginal arteries and closing of the vaginal opening. (2) Danger to the ureters. (3) In some women the os and cervix were the seat of sexual pleasure. (4) The cervix formed an integral part of the pelvic floor. (5) The opening into the vagina increased the chances of infection.

**Intrapelvic Adhesions.**—This paper was read by Dr. Walter B. Chase, of Brooklyn, N. Y. The author stated that in standard text-books on gynæcology very little space had been devoted to the distinctive topic of intrapelvic adhesions, and it was surprising to find how little notice on the whole it had received from writers on gynæcology and abdominal surgery. The character of the adhesions likely to be formed varied according to the variety of inflammation producing them. Recent adhesions lacked the strength and resistance of older ones, and the friability of those formed in the presence of septic, tuberculous, and malignant conditions was marked. The author then dwelt upon the diagnosis at considerable length. To prevent the development of adhesions, one must naturally prevent the occurrence of their antecedent septic and inflammatory processes. To retard their development two drugs had been long known —potassium iodide and mercurials; and to them must be added another—gold and sodium chloride. The Brand method of pelvic massage claimed recognition, and was undoubtedly useful. In the surgical treatment of these adhesions *per se* the danger was twofold —the difficulty of controlling the hemorrhage, and the liability of new adhesions forming from the exposed raw surface remaining. To control the hemorrhage, tying or torsion was recommended, or, when this was impossible, pressure, and the application of hot water or occasionally permanent pressure by gauze packing. Surgeons had encouragement for the future in the use of Dr. Skene's electro-hæmostatic method. To prevent the formation of new adhesions, as little raw surface as possible should be left, absorbable ligatures must be used, and what raw surface could not be covered was to be washed with decinormal salt solution.

The following officers were elected for the ensuing year: *President*, Dr. Rufus B. Hall, of Cincinnati,

Ohio; *Vice-Presidents*, Dr. L. H. Dunning, of Indianapolis, Ind., and Dr. T. J. Crofford, of Memphis, Tenn.; *Secretary*, Dr. William Warren Potter, of Buffalo, N. Y.; *Treasurer*, Dr. X. O. Werder, of Pittsburg, Pa.

Louisville, Ky., was selected as the next place of meeting in 1900.

## Correspondence.

### OUR LONDON LETTER.

(From our Special Correspondent.)

THE BRITISH ASSOCIATION; SIR MICHAEL FOSTER'S ADDRESS; WIRELESS TELEGRAPHY—OFFICIAL REPORT ON THE NAVAL MEDICAL SERVICE—A BLUE BOOK ON OYSTERS—JENNER INSTITUTE—SIR EDWARD FRY AGAIN.

LONDON, September 15, 1899.

THE British Association is holding its sixty-ninth annual meeting at Dover. This is to be distinguished from the Medical and other daughters who have taken the name British. The full description of this, the most important society of the kind, is British Association for the Advancement of Science, but the two words British Association alone are always understood as referring to it, and these are often abbreviated, sometimes as much as to the B. A. Medical subjects are not excluded, but must be viewed from a scientific point of view exclusively. The association is very popular, and the annual meetings in different towns are mostly well attended, not only by scientific workers but by many who feel an interest in the subject.

The association met on Wednesday, many members and friends having arrived on the Monday, and some on the preceding Saturday. In the evening Sir Michael Foster delivered his address as president. After referring to the losses sustained by the association through death during the year, especially to Sir Douglas Galton, who was chiefly responsible for the establishment of the National Physical Laboratory, he turned to the subject he had chosen, viz.: "The Progress of Science during the Nineteenth Century." This is certainly a large order, and could be only partially accomplished, but Sir Michael was able to please his audience with some bird's-eye views. Thus, he said, to-day our treatises on physiology are largely made up of exact expositions where our predecessors were obliged to resort to such vague terms as "vital force." Our present extensive knowledge of the nervous system was but an expansion of Charles Bell's new idea published in 1811. The middle years of the century marked an epoch in biological thought, for it was then that Darwin issued his "Origin of Species," a work that would have been impossible had not the earlier half of the century been in travail for its coming. The president pleaded on behalf of two great scientific projects—one, the Antarctic expedition, for which the association has voted £1,000. The other is a proposal for carrying out by international co-operation a complete current index of the scientific literature of the world.

Yesterday wireless telegraphy was to the fore, and gave Mr. Marconi another triumph. It had been arranged to exchange messages with the French association meeting at Boulogne. In order to intensify the currents a large cage of close wire netting was fixed to the mast-head at Dover, with very successful results. Messages were exchanged with Boulogne, the Goodwin lightship, and the South Foreland lighthouse. The ship is twelve miles out in the Channel, with four miles of high hills intervening between the sea and the transmitter at Dover. Numerous messages passed between members of the French and British associations, and the latter will pay a visit to Ostend on the 27th.

Professor Ogston's address was sure to excite criticism and widespread comment. Whether it had any effect in expediting the report of the committee appointed by the admiralty to consider the training for the naval medical service I cannot say; but that committee has just recommended a series of reforms. It pronounces the present course at Haslar to be insufficient. It recommends special instruction in diseases peculiar to foreign stations, and which must be met with in the naval service when abroad; serum therapeutics, including that of snakebites; ambulance drill, treatment of bullet wounds, and other branches of naval surgery; how to fit out a hospital ship; the use of the Roentgen-ray apparatus, and the photography connected therewith. These subjects are of such importance and so extensive that it is admitted some parts of the present course may have to be eliminated. An additional lecturer is recommended to be appointed, and three prizes are to be established. As a further stimulus to study the committee further recommends that the names of surgeons should not appear in the navy list until after they leave Haslar, and their seniority on the list should be determined by the marks obtained. Some other proposals are also made to enable officers on the active list to keep abreast of scientific progress. A recommendation which will give great satisfaction as removing a serious grievance is made respecting the surgeon's outfit. Hitherto naval medical officers have had to provide their own surgical instruments. The committee now recommends that all ships bearing medical officers, as well as naval and marine barracks, be provided with a set of instruments at the public cost.

Oysters seem on the way to a rehabilitation of character. A blue-book has just been issued containing the evidence submitted to the select committee appointed by the House of Lords. A number of expert witnesses were called. Dr. Bulstrode, of the local government board, says the bacillus of typhoid could not become a part of the flesh of the oyster without being first digested and therefore destroyed. The bacillus might be caught in the gills mechanically. The intestine might contain it, or the water in the shell if taken from a polluted bed, but even then it would not live long. Bacteriologists seems to agree that when an artificially infected oyster is placed in pure water, especially moving water, it gets rid of the infection within ten days. This will be pleasant reading to consumers as well as to the cultivators. But it certainly does not render less risky the planting of oyster beds near the outfalls of sewage.

On Wednesday, the changes necessary in the memorandum of association of the Jenner Institute to enable it to comply with the conditions of Lord Iveagh's gift of £250,000 were duly sanctioned by the court.

Sir Edward Fry has returned to his charge against the profession, but his letter to the *Times* is so full of blunders about the medical authorities and their powers that he only makes himself more ridiculous. Let him direct his attention to the black sheep of his own profession.

**Indications for Operations upon the Gall Bladder.**—(1) Cases marked by repeated attacks of gall-stone colic, which resist all treatment and are exhausting the patient's strength; (2) when there is evidence of suppuration about the gall bladder, due to gall stones; (3) in empyema; (4) in dropsy of the gall bladder; and (5) in obstructive jaundice, due to gall stones in the common duct.—ROBSON.

## FAITH CURE AND THE LAW.

To the Editor of the Medical Record.

Sir: I have just read your article on "Faith Curing in Illinois." I am not a Christian Scientist. There may not be any basis of truth for their claims as to curing people, but I am inclined to think there is such a basis. Of course Miss Eddy's book is mostly a conglomeration of nonsense, but the fact that Christian Scientists cure the sick is what influences people to accept their doctrine or theory as true. As far as human evidence can establish a proposition their "healers" cure as large a proportion of the sick as drug-physicians. Or what is the same thing to the sick as the "science," they are made to believe that they are cured.

Another point: I believe in giving sick people medicine, and I take some myself when I am sick. When I am very sick I like to take as little medicine as possible. Now suppose, although perfectly sane, I would conclude that I would not take any medicine at all. Would any person or organization have any right to make me take it? I think not. I never heard of such a proceeding.

If my child is sick and I think it should have medicine I effectually insist on its taking the medicine whether the child wants to take it or not. I do this because I feel responsible for the welfare of my child. I do not think the child competent to judge for itself, and so I exercise my judgment for it.

All will probably agree that I am right in this position. All will agree that I have the right to change doctors, and that I have the right to change from a "regular" to a "homœopath," or "eclectic," or the reverse. Some would question my wisdom in thus changing, but no one would think of doing so insane a thing as invoking "the law" to compel me to make a change or not make a change of said doctors. Why? Because they recognize my right to act for my child. Now suppose that for the good of the sick child I dismiss the drug-doctor and call in a faith or mind "healer," one who does not give drugs. At once some one raises the cry that I should be forced to have a "drug-doctor." Is this right? Is it just? Is it sanity? No, it is all wrong. Persuade me, if you can, to have a drug-doctor for myself or child, but don't try to force me to do either. You had better not. The argument used to justify compelling people to have a drug-doctor is that the sick person may die; yes, sir, may die! If a "mind healer" lets a patient die, a great hue and cry is raised against him, just as if no drug-doctor ever lost a case. If a drug doctor and a "healer" should each treat a hundred cases, the patients under each doctor being as nearly similar as possible, and the drug-doctor should lose ten of his hundred and the "mind healer" should lose only one of his hundred, there would be a great outcry against the "healer" and the family of the dead one, while hardly a remark would be made about the drug-doctor losing ten cases. The verdict would probably be that he had "pretty good luck" with his hundred cases, or "he did the best he could." Multiplied thousands of people die in New York City every year in spite of the best efforts of her many competent and painstaking doctors, and no one thinks anything of it, much less does any one denounce those doctors for letting those thousands die. But if a Christian Scientist or other "healer" lets one sick person die while being "treated" without drugs, at once every one connected with the case is denounced, and there is talk of "the law," and the incident is published far and near.

The childish absurdity of all this should be plain to every one, but it is not. We are blind worshippers of tradition, faithful trailers in old ruts, and loyal believers in the sacred and exclusive orthodoxy of drug medication as were our fathers. History repeats itself. Our grandchildren will smile when they read of our absurdities, eccentricities, and contradictions in these things. If a man wants for himself or child a doctor who does not give drugs, argue with him if you wish, convince him of his folly if you can, but don't talk about forcing him with "the law."

As to the "mind healer," "faith curist," or "Christian Scientist" (?), he will not "treat" any cases unless he is asked to do so, and he will not be asked to treat many unless he cures some; and the medicine doctor loses some of the cases treated.

I say all this although I am a strong believer in drugs. I take and give drugs, and if sick would have a drug-doctor. I plead for justice, fair dealing, and common sense in this matter.

N. C. Steele, M.D.

Chattanooga, Tenn.

## THE SMOKE NUISANCE.

To the Editor of the Medical Record.

Sir: The efforts of the New Yorkers to stop the smoke nuisance are quite pathetic to those who have been through a like experience in other cities. The claim that any one has a right to see the blue sky above or to breathe uncontaminated air below will be found to be absurd. Your wager (p. 453) is perfectly safe, even if you leave out the final clause. The nuisance will certainly increase so long as soft fuel is cheaper than hard. The economy is only for the consumer of coal, however. To the community the loss is great, in damage to clothing, house furniture and decorations, stocks of goods, impairment of health. The community simply pays all that the consumer gains, and much more. But the moment you interfere you are denounced as hostile to the manufacturer or to any large user of heat and power, and therefore to the city. The heavier the pall of smoke, the greater the prosperity.

No device yet attached to the furnace seems effective in overcoming the trouble. You must suffer more and more until electricity comes into universal use, and a few furnaces at convenient centres do the work of the thousands now running, or the force can be generated by water power at places more or less distant, and be distributed through the city by wires.

Rochester, September 25, 1899. *

## A VACCINE EXPELLER.

To the Editor of the Medical Record.

Sir: In your issue of September 23d "An Improvised Vaccine Expeller" is described by Dr. Boyer. Its object is to obviate the necessity of constituting one's self "a compressed air tank" in order to expel the vaccine from the capillary tube. He also mentions a "vaccine expeller" described in *The Lancet*, which, I should judge from the comparison made, is a rubber bulb, and considers his bicycle pump an improvement. When the capillary tubes of vaccine first came into general use some few years ago I had occasion to use them, and at first followed the health board's directions to "blow out" the virus. This did not please me for various reasons: the unpleasantness of putting things in one's mouth that the mouth was not designed for; the possibility of squirting saliva over the vaccine; the uncertainty of the amount of pressure from the "compressed air tank," which would sometimes suddenly shoot the vaccine out in all directions except where wanted.

A very simple expedient occurred to me that did

not necessitate the employment of any "mechanical apparatus." After breaking both ends of the glass tube and adjusting the small rubber tube in the usual manner, I simply take the free end of the rubber tube between my index finger and thumb, getting them in contact about a half-inch, or as much as possible, from their tips, at the same time holding their tips apart. This compresses only the end of the tube and practically makes a rubber bulb of it.

The tube lies between and parallel with the fingers, so that when the latter are gradually approximated from their point of contact toward their tips, the pressure expels the air from the rubber into the glass tube and forces the vaccine down. As only about a half-inch of the tube can be compressed in this manner, two such squeezes may be necessary to bring the vaccine out.

It is the simplest thing to do and perfectly under control, as the virus can be seen moving down the tube, and the pressure can be regulated accordingly. It is aseptic, clean, and convenient, and cannot be improved upon by any "mechanical apparatus."

It has also enabled me, when short of virus, to use one tube for two or three inoculations. Any desired portion can be forced out, and if the remainder is not to be used at once, a reversal of the forcing-out process will pull the vaccine back into the middle of the tube, and so allow of its ends being resealed by fusing them with a lighted match.

ARCHIBALD E. ISAACS, M.D.

240 EAST BROADWAY, NEW YORK.

## Medical Items.

**Contagious Diseases—Weekly Statement.**—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending September 30, 1899:

| | Cases. | Deaths. |
|---|---|---|
| Tuberculosis | 99 | 118 |
| Typhoid fever | 64 | 16 |
| Scarlet fever | 46 | 2 |
| Measles | 86 | 9 |
| Diphtheria | 158 | 20 |
| Laryngeal diphtheria (croup) | 8 | 6 |
| Cerebro-spinal meningitis | 0 | 5 |
| Chicken-pox | 3 | 0 |

**Climate of the Philippines.**—By some writers, and of course by a certain school of American politicians, the Philippines have been described as excessively unhealthy—a sort of eastern Bight of Benin, with the addition of constant earthquakes, periodic typhoons, and occasional epidemics of cholera. It is a common cry, familiar enough to Englishmen; but America need not be afraid that her new possessions will prove a white man's grave. Professor Worcester, it is true, complains much of the climate in his book, but in spite of his wide experience he does not appear—if he will pardon this expression of our opinion—to have acquired the rudiments of the art of travel. Without European food, without even flour, living on rice, oats, or anything he could find, often with no servants and insufficient means of protection against the weather, he naturally undermined his health and undoubtedly came very near his death from a severe attack of typhoid. It is not too much to say that similar exposure in a European climate would probably have been fatal. Mr. Foreman, undoubtedly one of the best authorities, gives it as his opinion that the climate of Luzon is excellent. Mr. Stevens describes the climate of Manila as much better than that of Hong Kong. Perhaps the best proof of these statements lies in the comparatively light mortality among the American troops in the present campaign. Beri-beri and cholera rarely attack Europeans, and the type of malarial fever is not a severe one. On the whole, for tropical islands they may be considered unusually healthy; less healthy, no doubt, than the islets of the Pacific, but far healthier than Borneo or New Guinea.—*English Quarterly Review.*

**Horseflesh as a Food.**—France is not the only country where horseflesh is popular; in Denmark it is preferred by many people to beef. Hippic butchers at Copenhagen have been in existence since 1830, and in Belgium for twenty years. In Germany and Austria business is brisk in horse-meat preparations, and is becoming more so every year. England is still reluctant about accepting the new aliment and classes that kind of food alongside snails and frogs. The first hippic butchers in Paris were only established in 1866; ever since that special trade is legally carried on, and is considerably increasing, as demonstrated by municipal statistics—so much so that to-day over five thousand tons of horseflesh are consumed annually in Paris, sold by sixty licensed horse-butchers, who receive supplies from two special hippic slaughter-houses, both outside the city proper. In both these abattoirs the sanitation is faultless, while the inspection of the meat itself is of the severest and most satisfactory nature, the same as for oxen, sheep, and pigs.—*Sanitary Record.*

**Golf and Neurology.**—It has been said, remarks the *Medical Press*, that every other man in America is now so addicted to Scotch ways and habits that he wears heather-tweeds, plays golf, drinks "Scotch," and says "Hoots, mon!" Of such must be Dr. Irving C. Rosse, of Washington, who contributed to the American Neurological Association a paper on golf from a neurological point of view. Dr. Rosse is evidently new to the game and knows little of its history, or he would know that fatal accidents have occurred, at least in Scotland, from golf-ball strokes. There is a great deal to be said in favor of golf for those suffering from heart lesions, arterial calcification, or certain hysterical conditions, and undoubtedly as a medical adjunct it is not to be despised. Dr. Rosse, while enjoining moderation, alleges that benefit has been derived in some cases of cough, nervous asthma, and in affections of bladder and prostate, but it is pre-eminently in functional nervous disease that our great Anglo-Saxon game is to be recommended both as a prophylactic and curative. As to its being a remedy for insomnia, there may be some doubt, as we have met within the last few days a golfer who, despite his golf exercise, suffered from insomnia. A great deal might be said in favor of golf as a mental and nervous tonic, but not to the exclusion of other sports which have many of the same advantages. Undoubtedly it is a good thing for the physician to know from his own actual experience the physical requirements of different games and their physiological uses. The use of golf as a remedy in the treatment of nervous ailments of a functional character, whether they affect the mental or visceral spheres, is worthy of all consideration.

**The Mouth as an Index to Character.**—A certain philosopher declares that a woman is known by her mouth—not by the words that issue therefrom, but by the shape and color of the lips and the lines and dimples that gather about this important feature. He is supported in his theory by physiognomists, who all endeavor to impress us with the fact that no woman with the small, red-lipped, "Cupid-bow" mouth, so praised in song and story, was ever intellectual or generous of heart. He says further that "it is con-

soling to those whose mouths are not in accordance with the lines of beauty laid down by the poets, to be told that a 'wide, straight mouth with strong, white teeth' denotes the woman of superior intelligence, goodness of heart, strength of mind, and a thousand and one other sterling qualities which we all like to think we possess." It is the fashion at present for women to hold their lips very slightly apart. This is supposed to give that innocent, wistful, wondering expression which was the peculiar property of the heroines of old-fashioned novels, but which bicycle riding and the kindred modern amusements have caused to vanish. It is difficult for the thin-lipped, determined woman to acquire this trick, but perseverance works wonders.—*English Outlook.*

**Influence of National Prosperity on the Marriage Rate.**—Dr. Farr has described the marriage rate as the barometer of prosperity, just as the funds are the barometer of credit. So we find that the marriages of England increase as "the result of peace after war, abundance after dearth, high wages after want of employment, speculation after languid enterprise, confidence after distrust, national triumphs after national disasters." The same conclusion is borne out by the fact frequently alluded to by the registrar general in his reports, that the marriage rate varies in the same direction as the value of British exports; the average price of wheat and the amount per head of population cleared out at the banker's clearing-house. The coincidence, it should be pointed out, is one in direction, but not in degree.—Dr. Newsholme on "Vital Statistics."

**The Multiplication of Congresses.**—The British Medical Association held a congress in July, when public-health subjects were more or less fully discussed; the Sanitary Institute Congress has recently had its session; that of the Royal Institution of Public Health opened on the 21st of August. Having regard to the sameness of subjects and speakers, we cannot help thinking that there would be much saving of "weariness of the flesh," much advantage to public-health science, if there were fewer opportunities of attacks of mental indigestion.—*Public Health.*

**Influence of Hereditary Diseases on Mortality of Children.**—Diseases in the parents are often accountable for weak children. In some instances these diseases cause the children to be prematurely born; in other instances the children are born at full term, but the iniquities of the parents are visited upon the children. Under this heading might be included alcoholism in the parents. The question of whether acquired characteristics can be transmitted need not trouble us; but it must be admitted that habitual drunkenness in the parents does tend to produce feeble children. Not only does drunkenness affect the children by causing the inherited capital with which the child starts in life to be deficient, but it also acts indirectly on the infant in this way, that often the surroundings are unhealthy and the mother neglects the child.—Dr. Thomas, in *Public Health.*

**Water Supply of Towns in Great Britain.**—*The Sanitary Record* says: "The exceptional heat of the past summer in Great Britain and the drought have had a very serious effect on the water supplies of the country. In the valley of the Thames the rainfall has been less than one-third of the normal quantity. The river has run low to an alarming degree, and the citizens of London are face-to-face with a repetition of the water famine, notwithstanding the facilities which the companies now possess of mutual assistance. No doubt the sufferers will derive much consolation from the assurance that the water commission will report in November. But it is not London only that is now threatened. From all parts of the kingdom comes the same tale of supplies running short concurrently with increased consumption. And in this connection one is constrained to remark on the deplorable thoughtlessness and lack of consideration displayed by so many people at a crisis such as this. Instead of exercising a prudent economy, they not only use the precious water with unnecessary extravagance, but they allow much of it simply to run to waste as if the supply were unlimited." The dwellers in American cities have reason to ponder over these remarks, for according to Sir William Preece the consumption of water in the majority of British cities rarely exceeds twenty-five gallons per head daily, while in New York sixty gallons and in Philadelphia ninety gallons are used daily.

**The Laughing-Plant of Arabia.**—An Indian medical journal publishes a description of a curious plant which grows in Arabia and in parts of the western frontier of Hindustan. It is popularly known as "the laughing-plant" on account of the effect produced by eating the seeds. "The plant is of moderate size with bright yellow flowers and soft velvety seed pods, each of which contains two or three seeds resembling small black beans. The natives of the district where the plant grows dry these seeds and reduce them to powder. A small dose of this powder has similar effects to those arising from the inhalation of laughing-gas. It causes the soberest person to dance, shout, and laugh with the boisterous excitement of a madman, and to rush about cutting the most ridiculous capers for about an hour. At the expiration of this time exhaustion sets in, and the excited person falls asleep, to wake after several hours with no recollection whatever of his antics."—*American Druggist.*

**Health Reports.**—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended September 30, 1899:

| | | Cases. | Deaths. |
|---|---|---|---|
| **Smallpox—United States.** | | | |
| Massachusetts, Everett | September 15th to 23d | 1 | |
| Tennessee, Memphis | September 15th to 23d | 1 | |
| Virginia, Portsmouth | September 15th to 23d | 1 | |
| **Yellow Fever—United States.** | | | |
| Florida, Key West | September 25th to 27th | 166 | 9 |
| Miami | September 15th to 23d | 2 | 1 |
| Louisiana, New Orleans | September 15th to 23th | 19 | 4 |
| **Smallpox—Foreign.** | | | |
| Belgium, Antwerp | September 2d to 9th | 1 | |
| Bohemia, Prague | August 27th to September 2th | 6 | |
| Brazil, Rio de Janeiro | July 29th to August 11th | 121 | 63 |
| Egypt, Cairo | August 15th to 27th | 1 | |
| India, Bombay | August 5th to 12th | 12 | |
| Greece, Athens | September 2d to 28th | 7 | |
| Mexico, Chihuahua | September 8th to 11th | | 6 |

### A CONTRIBUTION TO THE STUDY OF THE GASTRIC CRISES OF TABES.

By SEYMOUR BASCH, M.D.,

NEW YORK.

There is scarcely another symptom complex that, owing to the severity and intensity of its manifestations, is so likely to attract and to hold the interest of the physician as that form of nervous vomiting which, since Charcot's time, has been known as "gastric crisis." The individual features of these paroxysms have been discussed at length by celebrated authors, but many cases present peculiar phenomena which have not been fully enough dwelt upon, and there therefore remains much, especially from the diagnostic standpoint, which requires further study and explanation.

Delamare[1] was the first to call attention to the clinical connection between locomotor ataxia and its gastric phenomena (pain, vomiting, etc.). Charcot,[2] who gave us the first classical description and first carefully studied and analyzed the clinical and pathological features, named the attacks "crises gastriques." He and his pupils taught that gastric crises could occur only in connection with diseases of the spinal column. Notwithstanding that Couty[3] in 1876, Mistarlet[4] and Mathelin[5] in 1877 described and published interesting cases of purpura in which attacks of periodic vomiting occurred, the above view was generally accepted until von Leyden,[6] in a paper read before the "Verein für innere Medicin" of Berlin, reported cases of periodical vomiting which were similar to the gastric crises of locomotor ataxia, but in which, for many years, and in some cases even until death, no other characteristic symptoms of tabes could be detected. Von Leyden thought he recognized in these attacks a form of primary nervous vomiting occasioned by neuralgia of the pneumogastric nerve or of the cœliac plexus. With the exception of one case in which he had examined the pneumogastric nerve post mortem, there had been no examinations of the central nervous system made; nevertheless, he believed he could exclude all disease of the central nervous system in his cases. This declaration of von Leyden opened up an entirely new aspect of the question of periodical vomiting, and since his first publication, Rémond (of Metz),[7] Boas,[8] Immerman,[9] and recently Leclézio,[10] as well as Oettinger,[11] have published cases apparently confirmatory of his statement, but in none, unfortunately, have exact post-mortem examinations been carried out.

About the same time as von Leyden reported his cases, Quincke[12] and Dinkelacker[13] described cases of "acute circumscribed œdema" occurring in various parts of the body, particularly about the hands, with attacks of vomiting similar to those of gastric crises. Such œdematous areas had been observed in the mucous membrane of the pharynx, and the theory was advanced that the vomiting was due to the formation of similar areas in the gastric mucous membrane. More recently Struebing[14] has reported cases of a like nature. Debove[15] demonstrated a case in the "Société des hôpitaux" in which, following a blow upon the chest, severe periodic attacks of vomiting had occurred for six years, accompanied by most intense pains originating in the pyloric region, and radiating backward and upward between the shoulders. At the time of the demonstration not a single symptom of tabes was present. Grube[16] has described interesting attacks of vomiting complicating diabetes mellitus, but without symptoms of tabes. Matthieu[17] and his scholar, Baraton,[18] have observed similar attacks in cases of floating kidney.

It would lead us too far to recapitulate the historic development of gastric crises as they have been observed and described. Besides tabes and the primary nervous vomiting of von Leyden, periodic vomiting and gastralgias occur also in the following conditions:

1. Diseases of the central nervous system: (*a*) Organic (tumor and abscess of the brain, cerebral and spinal syphilis, dementia paralytica, multiple sclerosis, acute myelitis, and compression myelitis); (*b*) functional (hysteria, neurasthenia, migraine, irritations of the external auditory canal, etc., etc.); (*c*) diseases of the sympathetic (acute circumscribed œdema ["angioneurotic œdema" of Struebing], certain forms of purpura, Basedow's disease, etc.).

2. Diseases of the stomach: (*a*) Organic (ulcer, cancer, chronic atrophic gastritis, gastritis anacida, motor insufficiency of the second grade—so called ectasia—and perigastritis); (*b*) functional (gastrosuccorrhœa [chronica as well as periodica], habitual vomiting [so-called vomitus nervosus], and cardio- and pyloro-spasmus).

3. Reflex vomiting from other organs: (*a*) Diseases of the abdominal organs which are in communication with the stomach through the pneumogastric (liver, gall bladder, and kidney); furthermore, in gall stones, renal calculus, floating kidney, local and general peritonitis, abdominal tumors, ulcer and stenosis of the duodenum, chronic intestinal obstruction and hernia of the linea alba; (*b*) diseases of the sexual organs of both sexes; (*c*) diseases of the ears, œsophagus, pharynx, and also of other organs.

4. Constitutional diseases (gout, uræmia, diabetes mellitus, Addison's disease, malaria, etc.).

5. Chronic intoxications: (*a*) Metallic (lead, copper, and zinc); (*b*) medical (alcohol, nicotine, etc.).

6. Entozoa.

**Symptomatology.**—The gastric attacks in all these affections evidence in general like phenomena, varying, however, in their detail manifestations according to the underlying disease.

As described in the literature, typical gastric crises have the following characteristics: a very sudden onset without prior digestive or other cause; severe pains in the abdomen which, after remaining for a while in this region, extend upward and forward along the sternum to the neck, or radiate upward and backward between the shoulder blades. Accompanying these very often are lancinating pains in the lower extremities, and also severe boring or stabbing pains in the back, radiating laterally. In addition to these pains the

patients suffer from eructations and a choking sensation, which symptoms are soon followed by repeated and uncontrollable vomiting. Before and after this vomiting there are thirst, a feeling of pressure and of fulness in the epigastrium, anorexia, salivation, profuse sweating, and rapid prostration. So intense is the suffering that the patients toss about on their beds, assuming often the most extraordinary positions. Vomiting brings but temporary relief. The intensity and duration of the attacks vary, the duration being generally from three to six days. The attack ceases in as unaccountable a manner as its onset occurs. The pains and vomiting diminish gradually in severity and frequency. The patients fall asleep, to awaken entirely free from suffering, until after days, weeks, months, or even years, a new attack seizes them.

There are, however, many variations from this typical picture. An attempt has been made to classify them. Charcot[19] has described six irregular forms occurring in addition to the typical attacks: (1) a form with quite a typical course, but with unusual prominence of one of its manifestations; (2) a form marked by unusual severity of the pains with absence of vomiting; (3) severe vomiting with absence of pain; (4) a quotidian form (short daily attacks); (5) attacks of unusual length (fifteen to twenty days, or even a month); (6) a form known as "vomissements noirs."

Fournier[20] describes a very peculiar variety which he has but once observed, and to which he has given the name "la variété flatulente de la colique gastrique." Here, without special cause, there occurred for periods of days and weeks loud eructations of odorless and tasteless gases, with no marked vomiting, however. His description reminds one very much of the "eructatio nervosa" of hysterical and neurasthenical persons, such as have been described by Oser,[21] Bouveret,[22] Boas,[23] and others. Fournier[20] has also described what he calls "anorexie tabétique," an ordinary type of gastric crisis, in which obstinate loss of appetite, defying all remedies, forms the most prominent symptom. The patients force themselves to take food to prevent collapse. He reports a case in which loss of appetite had existed for over nine months.

If we now pass to our own cases, and carefully analyze all the phenomena which they present, we can but come to the conclusion that a strict classification of gastric crisis, as just detailed, is not warranted. In conformity with the cases described at length in literature, we find even in the same patient the greatest variations regarding the duration, frequency, and other features of the attacks. The material which I have had the opportunity of observing and studying consists of twenty-two cases treated at various periods from 1892 to 1898 at the polyclinic of Dr. I. Boas, of Berlin, and of three cases from the polyclinic of Prof. H. Oppenheim, of Berlin, these cases being kindly placed at my disposal during my assistance at Dr. Boas' polyclinic. These patients are mostly of the laboring class, seventeen being men and eight women, a proportion of two to one. According to Friedrichsen,[24] who has carefully studied the statistics of tabes dorsalis abroad, among six hundred and seventy-six cases in the most prominent clinics of Berlin, the proportion of men to women was 4.4 to 1.

The majority—nineteen—of our patients were between thirty and forty years old, three being under thirty and three over forty. Rosenthal[25] calls attention to the preponderance of gastric crisis in the fourth and fifth decennium. It would seem that the puerile age enjoys freedom from these attacks. Hildebrandt,[26] who has studied all published cases of tabes in children, points out that in none of these have gastric crises occurred. On the other hand, we frequently meet with "juvenile vomiting" (v. Leyden), which consists of a series of dyspeptic symptoms in consequence of poor and deficient nourishment, intestinal parasites, hysteria, over-exertion at school, etc.

No history of heredity of the crises could be obtained from our cases, nor does syphilis appear to play any important etiological part. In only five cases could a positive history, and in three others a probable history, of a specific infection be obtained. Fournier[20] found among two hundred and twenty-four cases of tabes with distinct syphilitic infection only fifteen (six per cent.) with gastro-intestinal symptoms (exclusive of rectal cases) in the initial stage. This is very small indeed, for gastric crises occur far more frequently in the earlier stages of tabes than in the later. According to Roestel,[27] gastric crises occur in thirty per cent. of all cases of tabes.

Trauma could be considered as a possible etiological factor in but one case. This patient, a smith, had frequently to hold against his abdomen a piece of metal upon which blows were struck with a hammer. This procedure occurred once directly after eating. He immediately began to vomit, and since then, at intervals of several weeks, has been taken with unaccountable attacks of severe vomiting, sudden in their onset, and frequently associated with profuse diarrhœas (enteric crises?).

The majority of our patients stated that their attacks occurred suddenly and without any assignable direct cause. A few regarded them as a consequence of mental excitement, or of errors in diet. The latter cause does not seem plausible in view of the fact that their digestion before as well as after the attack appears to be normal: a conclusion drawn from the general good appearance before the attack, and the rapid convalescence thereafter.

It is a fact that gastric crises may continue until advanced life, or until the very last stages of tabes. Charcot,[19] Pitres,[28] Boas,[*] Kahler,[29] Rosenthal,[25] and others have published cases whose duration did not, however, exceed ten years; Buzzard[30] three cases of twelve, fifteen, and seventeen years respectively, while Gowers[31] reports in his book one of eighteen years' duration, which was still in the first stage of tabes. Our polyclinic material also presents striking examples, the shortest duration being one and one-half years, the longest nine and one-half, ten, and even fifteen years.

The length of the single attacks varies also within wide margins—from ten to twenty-four hours, up to three and to six weeks, the majority lasting from one to seven days. In five cases there were attacks of almost continuous vomiting and pains, extending over several months. In all cases except two (morphinists with atypical courses) the symptoms continued day and night. Only a very decided minority declared their symptoms worse at night.

The same patient at times manifested a remarkable regularity, at other times a striking irregularity, in the duration of the single attacks. For example, one patient, with a ten years' history of gastric crises, informed me that the first attack lasted three weeks uninterruptedly day and night; the second attack occurred after an eight weeks' cessation and lasted six weeks, with short daily remissions. After a brief time it was followed by short daily attacks for a period of two years; thereafter there was a short interval, followed by attacks lasting from two to five days. This last condition continues to the present date.

As a rule, the duration of the intervals between the attacks also varies very much. Patients frequently state that the attacks occur at regular intervals, but close inquiry into our cases, and analyses of those reported by others, reveal an entirely different condition. To illustrate, a railroad employé who had stated that his attacks had occurred at first tri-monthly, later in ten-weekly, and finally in six-weekly periods, noted carefully the dates upon which he had been excused

from duty because of the attacks; from these data it was clearly shown that there was an entire absence of any regularity in the frequency of the attacks. One case, the patient suffering ten years from gastric crisis, is worthy of note because the interval became gradually shorter (first one year, then half a year, and gradually a lesser interval; since two years a very irregular interval of from one day to two weeks). Another case displays just the contrary condition, at first daily, then weekly pauses. In two cases the attacks for years have occurred synchronously with the menses.

Furthermore, we find no unanimity regarding the degree of intensity with which the attacks begin. All patients stated that the attacks were ushered in unexpectedly. In twenty-one cases the intensity of the attack reached its height in a short time; while in only four cases the full development was gradual. Of these twenty-one with acute onset, thirteen began with severe pains in the abdomen, in the back, or in the side of the body; one began with cephalalgic symptoms such as accompany the so-called "crises ophthalmiques" of Pel[32]; seven began either with profuse diarrhœas accompanied by severe cramps in the abdomen or with symptoms of acute gastritis (nausea, epigastric pressure, loss of appetite, etc.). Three of the above four cases (*i.e.*, those with gradual development) began with gastric symptoms lasting from several hours to two or three days, while the fourth case began with peculiar prodromes to be described later.

If we now compare the relative intensity, duration, and frequency of the single attacks with reference to their increase, diminution, and stability in the progress of the disease, we find, with the exception of one uncontrollable case, the following relations:

| | Increased. | Diminished. | Stationary. |
|---|---|---|---|
| Intensity | 0 | 10 | 14 |
| Frequency | 8 | 8 | 8 |
| Duration | 1 | 6 | 17 |

Depending upon the frequency and intensity of the attacks and the stage of tabes to which they have advanced, the general condition of the patients varies very much during the intervals. If the gastric crises occur in the early stage of tabes, the general condition during the interval is, as Charcot[2] and other authors have declared, a comparatively good one; when occurring frequently and with great severity, we generally see a condition developed similar to chronic dyspepsia or chronic ulcer of the stomach (cibophobia). Such patients take very little food for fear of bringing on an attack, and chronic inanition accompanied by neurasthenic phenomena ensues. As a consequence we have noted very great loss in weight in some of our cases of severest gastric attack. For example, one patient, suffering two and one-half years, lost during the first four months sixty pounds, and during the entire period one hundred pounds; another, eighty pounds in one year and a quarter; another, seventy-five pounds in fifteen years. It seems that loss in weight progresses far more rapidly in corpulent persons. Two patients, sparsely nourished before their attacks began, had lost very little in weight, although suffering frequently and very severely during many years. When free intervals of comparative length exist, the patients seem to regain their loss in weight quite rapidly; thus, in one of our cases in which the attacks had ceased since March, 1898, the patient had gained twenty-seven pounds by January, 1899.

Charcot and the French school, as well as others, have pointed out that gastric crises generally begin with intense lancinating pains in the legs. It appeared to me of interest to verify this assertion, for Vulpian,[33] Charcot,[19] and Buzzard[30] have advanced the theory that both lancinating pains and gastric crises are occasioned by analogous anatomical changes;* the latter due to degeneration of the nucleus of the pneumogastric, the former to degeneration of the posterior spinal roots. Only in five of our cases did the attacks begin with lancinating pains in the lower extremities.

Charcot[19] taught that either pain or vomiting may be absent. In none of our cases was vomiting absent, and pain in but three. Pain, when at all present, formed the most prominent symptom of the entire attack, but seldom continued after the latter's subsidence. It manifested itself, however, differently in different cases. In only one case did the pain, analogous to the description of Charcot,[2] begin in the iliac region, extending from here upward over the abdomen, either fixing itself in the epigastrium or radiating toward the back. In other cases the localization of the pain was various. While in one instance it appeared as tearing and stabbing in character, located in the back and radiating around the sides to the front of the body, in others it began as a griping or burning in the epigastrium, extending through to the back or upward along the sternum into the neck. All these pains were intermittent and beneficially influenced, if only temporarily, by the vomiting. Many patients, again, complained of constant boring pains in the back or in the sides of the chest, which pains appeared as the first symptom of the gastric attack and were constantly present throughout. Occasionally in the beginning, a strong girdle-sensation, that subsided with the vomiting, would accompany the crisis. In some, different varieties of pains were present. Frequently a pain, beginning in the back, would later appear in the epigastrium and remain there constantly during the entire attack. In three cases it was not present in any of the above forms, but gave place to a constant feeling of pressure in the pit of the stomach, and an intense choking sensation in the chest, combined with extreme nausea and anxiety. In the majority, the vomiting either ameliorated the severity of the pain or even caused it to disappear entirely. The patients soon learned to recognize this, and resorted to various mechanical ways to bring about emesis.

The quantity of the vomited matter was, as a rule, enormous; I have repeatedly seen patients who had not taken fluids for two or three hours, vomit several litres.† The vomitus, which has been examined and described by many writers, consisted usually at first of macroscopically recognizable food remnants, later of acid stomach secretions mingled with mucus, and finally of tasteless, clear mucus, or of bile-colored fluid. When there was protracted vomiting, traces of blood could be occasionally observed. Vulpian[33] and Charcot[19] have described cases in which the vomitus had at first the usual characteristics, but later took on coffee-grounds appearance ("vomissements noirs"). I have never observed this condition in any of our patients.

Sahli's assumption[34] that the vomited matter contained a large amount of hydrochloric acid, and that this fact might prove of diagnostic value, appeared to be substantiated by the examinations of Kahler,[29] Simonin,[31] Rosenthal,[36] and Hoffmann[37]; but later was thoroughly refuted by other investigators, especially by von Noorden.[35] I contented myself, therefore, with the chemical examination of the vomitus in but five cases—in each instance at the height of an attack—and was convinced thereby that the assertions of the last-mentioned author were fully correct.

* *Cf.* Buzzard: British Medical Journal, March 5, 1881, p. 333, and The Lancet, September 24, 1881, p. 540.

† On the other hand, one patient who had suffered for six years from severe attacks of eighteen hours' duration, stated positively that he had never, excepting when he drank large quantities of fluid, vomited more than half a litre *in toto*.

In Case I. of these five, two examinations on the third day of the attack showed in the one instance neutral reaction with litmus, while the second, slightly acid with litmus, gave negative reaction with Congo paper (no free mineral acid); Case II. showed strongly positive reaction with Congo paper, and a total acidity of 42; Case III., Congo paper strongly +; total acidity, 60; Case IV., Congo +; total acidity, 45; while Case V. showed an acidity of but 25. The vomitus in a number of other cases was also tested with Congo paper, but the results obtained therewith were various, a positive reaction being frequently lacking. Repeated microscopical examinations showed nothing pathognomonic. In the beginning there were only food remnants, later leucocytes, and occasionally erythrocytes, squamous, cubical, and cylindrical epithelium; the latter was always increased proportionally to the duration of the attack, especially when there was a marked amount of bile in the vomitus. On the other hand, there never were any particles of mucous membrane or sarcinæ present. In vomited matter with HCl values we frequently observed "Jaworski bodies" (groups of cell nuclei alone without cell protoplasm) Once, on the third day of an attack, bodies insoluble in ether and very much like tyrosin crystals were seen.

Of our twenty-five patients, twenty-three suffered from absolute anorexia during their gastric crises. The remaining two, notwithstanding constant nausea and epigastric pressure, had a lively appetite throughout, but in spite of this refrained from eating, for everything would be immediately vomited. I expected to find high acid values in their vomitus, but this was never the case; the acidity was constantly within normal limits (40–60).

The condition of the abdomen is of importance in the differentiation between nervous vomiting and vomiting that accompanies acute inflammatory conditions of the abdominal organs. In moments of severe pain, during an attack, the abdomen was found more or less retracted, never protruding or tympanitic, while in comparatively painless moments it was soft and flat. In this connection I should like to emphasize that in no case did either palpation or percussion produce any pain whatever. On the contrary, patients even frequently resorted to frictions and stroking of the abdomen, believing thereby to obtain relief from their disagreeable symptoms.

In conformity with all other authors, I can state that I never found fever or a distinct chill at any time during the attack, though it is true a chilly sensation was an almost constant concomitant. The pulse, as Charcot [2] first taught, was rapid at the height of the attack (110–130), while in the quiet moments it would sink to 80 or 90. Rosenthal [22] has observed a pulse as low as 50–60 in one of his patients, an anomaly which I never discovered.

With the exception of one case the sensorium was always intact. This patient, presenting a classical picture of tabes, suffered from most typical crises of two to five days' duration, during which he repeatedly had attacks of syncope, analogous to the two cases published by Hoffmann.[27] I have frequently observed him during such attacks of syncope. They usually came upon him when the pains and the vomiting reached an acute stage, as follows: the face suddenly became very pale, the lips blue, and, without uttering a sound, the patient became unconscious; at the same time he was seized with tonic convulsions of the entire body and clonic twitchings of the fingers, the mouth being firmly closed and the eyes half open. There was total absence of pupil reflex, and no strabismus. The respiration became shallow and quiet, scarcely perceptible, the skin pale and cold, and the pulse very rapid (140–150). This condition lasted from five to ten minutes; the cheeks then became suddenly flushed, warm perspiration broke out over the body, and consciousness soon completely returned. After such an attack the patient complained of great fatigue, and was free from pains and vomiting for a long time. I have convinced myself of the total unconsciousness of our patient by mechanical irritations, etc. Formerly such attacks of syncope were followed by cessation of the crisis; the patient would recover very quickly and pursue his customary occupation. Of late, however, this was no longer the case; the symptoms of the crisis returned with usual severity after a few hours. Whereas formerly he had but one such attack of syncope, he now suffers from several (three, four, or five) during a crisis of from four to five days. Examination of the circulatory system showed marked arteriosclerosis, but no enlargement of the heart.

In the majority of cases the urine was markedly diminished and frequently darker than normal. In some however, normal quantities were passed during the attack. In one case complete anuria was noted, not followed, however, by unusually large quantities of urine as the attacks passed off (contrary, for example, to hysteria). A decided diminution in the quantity of the urine is to be expected when we consider what enormous quantities of fluids are vomited, and how little the patients drink during an attack. The urine was always normal, both chemically and microscopically; the specific gravity naturally was higher than normal.

During the gastric crisis, von Noorden[39] found acetone and diacetic acid almost constantly present in the urine. In three patients these bodies were present each time, but I did not enter more fully into the question because acetonuria is well known to be an accompanying symptom of inanition, and because von Noorden himself says he has found these bodies just as frequently in nervous vomiting from other causes as in that due to tabes.

A total change regarding the character of the attacks occurred in two cases. In the one case of ten years' duration, the attacks formerly began with epigastric pains, which ceased, however, as soon as vomiting took place. The latter continued for several days and formed the most prominent feature of the attack. After two years a change took place; the pains, no longer epigastric but dorsal, constituted the principal symptom. They would occasionally radiate around the sides toward the epigastrium, causing such painful girdle sensations that the greatest dyspnœa and anxiety on the part of the patient ensued. With but momentary remissions, the pains continued day and night, constantly increasing in severity. The attacks lasted about eight days, disappearing suddenly.

The second patient has suffered for fourteen years from typical gastric crises, with vomiting as the main symptom. About three years ago, during the free intervals, isolated pains occurred, at first in monthly periods, but since the beginning of 1898 in daily ones. The pains are as follows: (1) Severe stabbing pains in the dorsal region, which, lightning-like, radiate right and left around the sides toward the sternum and epigastrium; (2) a strong burning pain which encircles the body like a tight girdle. Both types begin usually in the morning, remaining till evening, when they suddenly disappear. Although the patient partakes of food, vomiting never occurs. At times, especially in winter and during bad weather, the attacks continue for several days. As accompanying symptoms the patient mentions anorexia, obstinate constipation, great anxiety, and depression. Personal observation confirms his statements. Notwithstanding the intense pains, the abdomen was soft, could be well palpated, was nowhere painful to the touch, nor could contracted coils of intestines be felt.

**Complications.**—The gastric crises in a number of our cases were complicated by other interesting conditions. Two patients suffered also from laryngeal crises (sudden attacks of choking with paroxysmal dry cough, frequently accompanied by severe sneezing, all of which lasted but a moment or two). One of these patients suffered from his laryngeal attacks seventeen years prior to the gastric, and the only other symptoms of tabes, when first seen by us, were lancinating pains in the extremities, and numbness in the fingers. Later typical symptoms of tabes developed. Two patients suffered from enteric crises appearing always simultaneously with their gastric crises, while a third had enteric attacks alternating with the gastric ones. The picture of tabes as presented by another patient was complicated by symptoms of dementia paralytica. I would like to report one case in detail, because complications of gastric crises, such as I cannot find elsewhere described, were here present.

N. K——, aged twenty-four years, formerly variety singer, married since 1895, suffers from typical gastric crises lasting eight to nine days, and occurring at first at intervals of one to two weeks, later of two to three months, but since 1897 of four to six weeks (frequently synchronously with menstruation). Toward the end of each attack, and for two or three days thereafter, without any pain whatsoever she passes, during defecation, large shreds of mucous membrane up to a foot and a half in length. At our express wish, patient paid special attention to this phenomenon, and reported that she never passes any mucous shreds excepting toward the end of an attack. Repeated rectal lavage during the interval between the crises seldom brought out even traces of mucus, and never pieces of membrane. When first observed (1896), the patient presented no other signs of tabes for many months. Syphilis was stoutly denied, although there was and still is a painless annular stricture of the rectum. The patient disappeared, but returned after a year. The crises had continued as before, but with more severity, and her general appearance was markedly worse, she having lost eighty pounds in weight. Examination now showed girdle sensation, absolute loss of pupil reflex, absence of patellar reflex, incontinence of the bladder, and paræsthesiæ of the face, between the shoulders, and in the calves of the legs. In June, 1897, sight began to diminish; to-day there is total blindness in consequence of optic atrophy.

From the study of our cases we see that, as has been already stated, the manifestations of the gastric crises are many and varied. An analysis of cases reported by others also serves to prove this point. Therefore it would be better perhaps to lay aside any tabulation based upon frequency, duration, and intensity of the attacks. For the purpose of simplification, and for a better comprehension of the various types, I would propose the following subdivisions: (1) Gastric crises with sudden onset. (2) Gastric crises with gradual onset. (3) Gastric crises with marked prominence of isolated manifestations, *e.g.*, "anorexie tabétique" (Fournier), "variété flatulante" (Fournier), "vomissements noirs" (Charcot), etc.

All these forms may be accompanied either by pain or vomiting, or by both.

**Diagnosis.**—The recognition of gastric crisis may be very difficult. If, however, the diagnosis of tabes itself be clear, and the case not complicated by any of those conditions which may give rise to attacks resembling gastric crisis (*vide supra*), the correct diagnosis should easily be made. In these cases mistakes can alone arise if the nervous system of the patient be insufficiently examined; an oversight which is by no means unlikely when symptoms from the digestive tract so fully occupy one's attention. The difficulty will be all the more enhanced if the gastric crisis occur as one of the very early symptoms, or if the clinical picture of tabes be an atypical one. Buzzard,[39] Pershing,[40] Wernei,[41] Charcot,[19] Vulpian,[33] Rosenthal,[25] and others have reported cases very strongly illustrating these points. In the following two patients, we see good examples of atypical cases of tabes in which the diagnosis can be made only through a careful examination of the nervous system:

Case I.—M. D——, widow, aged forty-four years, previously well, no hereditary history, was referred to us in June, 1897, as suffering from "some stomach trouble." The patient at that time stated that she had suffered for three years from severe attacks of periodic vomiting, always lasting about eight days, and that she felt perfectly well during the interim. Careful questioning elicited that she had had lancinating pains in the lower extremities for several years, frequent vertigo, a sensation at times as though walking upon needles, and, furthermore, that within a period of two weeks all her teeth excepting ten had fallen out without any pain or caries. Objective examination showed strongly increased patellar reflex, normal pupil reaction, and no ataxia or Romberg symptom. Posteriorly there was an area of anæsthesia extending from the left suprascapular region to the ninth dorsal vertebra; in addition hypalgesia in various parts of the body, especially about the shoulders and in the mucous membrane of the mouth. The diagnosis of tabes with gastric crises, then made by me, was confirmed by Professor Oppenheim of Berlin. Examination in August, 1898, showed absolutely no change in either objective or subjective symptoms.

Case II.—M. S——, teacher, aged thirty-eight years, no hereditary history, no previous illness excepting a slight attack of appendicitis, has suffered for eight years from periodic attacks of vomiting associated with severe pains. They occurred during the first two years every three to six weeks, but since then every eight to fourteen days. They invariably begin in the morning apparently without any assignable cause, and, after continuing from ten to twenty hours, disappear quite suddenly. The patient states that each attack has the following prodromes: uneasy sleep, early awakening, feverish and depressed feeling, inexplicable anxiety, heaviness of the extremities, and a rapacious appetite. This condition continues a few hours, and is succeeded by intense tearing pains along the spinal column, nausea, tasteless and odorless eructations, strong salivation, and such an irrepressible desire to vomit that the patient is finally forced to produce emesis by artificial means. The symptoms increase in severity very rapidly, and, with interruptions of from one to five minutes, continue until the attack suddenly ceases. The vomited matter is always abundant, but contains nothing of special diagnostic value. The urine is suppressed during the entire attack, but examinations made at other times show it to be normal. The case is, moreover, interesting, in that frequently in the beginning of an attack a scarlet, macular eruption appears upon the front and sometimes upon the sides of the thorax, disappearing shortly after vomiting occurs. Vulpian[42] describes a like phenomenon in his case of "vomissements noirs." The physician who had at first treated the patient found the right kidney dislocated to the second degree, and as repeated examinations failed to reveal further symptoms of tabes other than the Argyll-Robertson pupil and also inequality of the pupils, tabes was excluded and the condition of the kidney regarded as the cause of the attacks. The patient thereupon wore two different kinds of "kidney corsets" for a number of years. But despite these, his attacks continued, and he became very much emaciated. Soon after he was frequently seized, while at his meals, by paroxysms of coughing which threatened to choke him, but which disappeared very suddenly a

moment or two after their onset (laryngeal crises). The patient about this time consulted Professor Oppenheim, who made the diagnosis of locomotor ataxia. The gastric and laryngeal attacks continue with unabated severity to the present day. In addition to his other symptoms there are now anæsthesia of the skin and of the left breast, and of late also difficulty in urination. The patellar reflex is absolutely normal; there are no disturbances of co-ordination, no Romberg symptom, no lancinating pains, no girdle-sensation, nor in fact any other symptoms of tabes present. There can be no doubt, however, as to the correctness of the diagnosis, tabes, in this case. In the beginning it may have been justifiable to refer his attacks to the dislocated kidney, but with the onset of his laryngeal crises the diagnosis, according to Charcot,[19] admits of no further doubt.

Since, therefore, in cases in which a number of typical symptoms are present the diagnosis of locomotor ataxia is either overlooked or medical opinion is divided as to the diagnosis, how much more cause for error do those cases present in which gastric crises form the prominent symptom? This latter condition is by no means so rare as is generally believed. This fact is not sufficiently emphasized in text-books, but numerous examples are not wanting in literature. Charcot, Vulpian, Kahler, Pitres, Boas, von Leyden,[43] Rosenthal, and others have published instructive cases in which gastric crises constituted the only symptom for years, and which had been diagnosed as hysteria, neurasthenia, and not infrequently as atony, cancer, catarrh, or other disease of the stomach of which pain or vomiting forms an accompanying symptom.

If gastric crises be the only clinical manifestation, the diagnosis of locomotor ataxia cannot be made with certainty, for this requires the presence of at least two classical symptoms. Since typical gastric crises have well-defined characteristics, their recognition in time may at least serve to indicate the possible existence of the central nervous disease. These characteristics are: (1) Absence of symptoms of organic disease of the gastro-intestinal tract. (2) Sudden onset. (3) No initial chill. (4) Great intensity of symptoms, sometimes rapidly, sometimes gradually increasing in severity. (5) Rapid pulse with no fever. (6) Absence of any local condition in the region of the stomach, and absence also of other factors to explain the severity of the symptoms. (7) Absence of specific diagnostic features in the vomitus. (8) External circumstances have no influence upon the natural course of the attack (*cf.* remarks under "Treatment"). (9) Spontaneous cessation. (10) Rapid convalescence.

**Differential Diagnosis.**—It is not within the province of this article to enter into the differential diagnosis between locomotor ataxia and all those conditions which give rise to phenomena similar to the gastric crises (see above). It is assumed that when a physician is called to a case of vomiting or of gastralgia, he thinks of the possibility of a central nervous disease, and in this connection I would emphasize again that locomotor ataxia is especially to be thought of if the patient be in the fourth or fifth decennium of life.

The positive diagnosis of the genuine gastric crises rests naturally upon the diagnosis of locomotor ataxia itself. In conformity with most authorities we look upon the lancinating pains, diminution of sight, failure correctly to recognize difference in colors, Argyll-Robertson pupil, girdle sensation, and the absence of patellar reflex, as the most valuable signs of this disease.

I would like to dwell upon the points of differential diagnosis between genuine gastric crises and ulcer and cancer of the stomach, perigastritis, gastro-succorrhœa, functional nervous vomiting and gastralgias, duodenal ulcer, cholelithiasis, cerebral vomiting, and the vomiting of uræmia.

All the above conditions have much in common with gastric crises, *e.g.*, suddenness of onset, vomiting, pain, prostration, intense feeling of illness, periodicity with intervals in which the acute stomach symptoms diminish or entirely disappear, etc.; but each condition is marked besides by certain typical characteristics:

I. Differentiation from Ulcer of the Stomach: This affection, it seems, has caused errors in diagnosis more frequently than any other. However, the nature of the pain and the character of the vomiting ought to enable us to differentiate sharply in the majority of cases. Pain in ulcer of the stomach begins a short time (about one-half hour) after the ingestion of food, is of a burning, gnawing, or stabbing character, and is located at a fixed point in the epigastrium. It is markedly increased by even the slightest pressure, and may radiate to the back. There is a close connection between the time of ingestion of food and the vomiting, the latter taking place at the height of digestion. Emesis always ameliorates pain or causes it to cease entirely until after the next meal. The vomited matter in ulcer has in addition two characteristics of diagnostic value, viz., a large amount of free hydrochloric acid and the presence of blood. Of course these last two features may be absent; their presence alone is of positive diagnostic worth. Furthermore, the character of the food is of decided influence in the causation of the pain of ulcer; bland diet always brings relief. As we have already seen, all these points lose their diagnostic weight in gastric crises. In the latter, if relief at all follows emesis, it is but momentary.

The difficulty in diagnosis will arise rather in atypical forms of ulcer. It is well known that ulcers may exist for years without being diagnosed, until their presence is finally revealed through hemorrhage or through the development of sequelæ (perforation, dilatation, perigastritis, etc.). In the absence of tabetic symptoms other than the gastric crises themselves, it may frequently be impossible to differentiate the two conditions. By remembering the characteristics of the gastric crises as previously tabulated, we will, in many cases, be guarded from error in diagnosis. I would emphasize especially that gastric crises are typified by the absence of any directly assignable cause for their onset, by the absence of a local condition in the stomach to explain the severity of the symptoms, by the inconstant character of the vomitus, and by the absence of gastric symptoms between the attacks.

The quotidian form of gastric crisis is also likely to give rise to error, for here attacks are much milder than in the other forms, and the symptoms usually cease with the act of vomiting. The recognition of the true condition will not be at all difficult if we recall that the attacks in gastric crises occur independently of ingestion and character of the food; that there is no local condition of the stomach to explain the symptoms; that the symptoms characteristic of ulcer, viz., bulimia, distress and pressure after eating, sensitiveness to pressure of clothing, etc., are absent between the attacks, and that our patients are well nourished (for we have but to differentiate cases in the early stages of tabes).

Finally, we must remember that ulcer of the stomach occurs almost exclusively in young persons, while locomotor ataxia seldom begins before the twenty-fifth year.

II. Differentiation from Ulcer of the Duodenum: In this affection we meet with periodic vomiting and gastralgias, severe in character, and occurring often independently of the time of food ingestion. The history is here important. In chronic cases we learn of the

frequent occurrence of dyspeptic symptoms and of pain in the epigastric region, usually somewhat to the right of the median line, occurring two or three hours after meals and generally increased by external pressure. Frequently there is blood in the fæces, occasionally in the vomitus. The attack itself, however, forms the greatest point of differentiation. Vomiting—at all events continuous vomiting for several days—is quite infrequent in duodenal ulcer. Exquisite sensitiveness to pressure in the region of the duodenum, although not constant, when present is a sign of great importance. This pressure sensitiveness is said to be isolated in the right hypochondrium. Usually in gastric crises the abdomen is not sensitive to pressure, and in the few cases which are so this is not isolated, but occurs over the entire abdomen. In a number of cases of duodenal ulcer we find icterus present, which is a condition not at all found in gastric crisis.

III. Differentiation from Perigastritis: This sequela of ulcer of the stomach deserves a few words of special mention, since it may easily be mistaken for that form of gastric crisis characterized by pain without vomiting. Here the history is of the greatest importance. We should always inquire for a history of ulcer or its principal clinical manifestations. If our inquiry elicits no positive facts, then the diagnosis, perigastritis, may still be made with certainty, when pain is localized in the region of the stomach; is tearing or drawing in character; occurs after eating or drinking; and is very little or not at all increased by pressure. The pain in perigastritis is produced only in certain positions of the body (standing position, etc.), and is never so persistent as that of gastric crisis; it disappears with vomiting or toward the close of digestion.

IV. Differentiation from Cancer of the Stomach: Notwithstanding the frequency with which gastric crises have been mistaken for this condition, careful consideration should lead us to exclude easily all forms of gastric crises excepting those rare ones of "vomissements noirs."

In those advanced cases of locomotor ataxia in which emaciation and weakness are so extreme as to lead us to suspect cancer, the diagnostic symptoms of tabes must be so typically present that only neglect to make a general examination can produce an error in diagnosis. A suspicion of beginning cancer may arise, if in an individual between forty and sixty years of age, who had always been previously well, gastric crises should suddenly occur. Brief deliberation, however, would clear up the case, for the manifestations of gastric crises contrast markedly with those of beginning cancer. The latter develops usually as a chronic gastric catarrh, and, in contrast to the clinical picture of gastric crises, symptoms of an organic stomach disease are never absent.

A cancer may develop from a former ulcer, but the manifestations then would be decidedly those of the latter affection, and what I have already said regarding the differentiation between ulcer and gastric crises applies fully to cancer of this special class. The points which would here especially speak against gastric crises are the presence of an etiological factor (ulcer), a local condition of the stomach region sufficient to explain the symptoms present (tumor, pain on pressure, stenosis with or without dilatation), the presence of diagnostic factors in the vomited matter (lactic acid, blood, cancer cells), and finally, the influence of dietetic measures upon the course of the attack.

The reports by Charcot and Fournier of two cases of "vomissements noirs" are unaccompanied by chemical examinations. It is probable, however, that here, as well as in the ordinary gastric crises, no lactic acid was present. In the absence of local objective conditions in the stomach during such attacks of "vomissements noirs," and of other tabetic symptoms, and in the absence of a history of emaciation (which latter always develops in cancer), the future course of the disease alone can establish the correct diagnosis. In no instance, therefore, should careful chemical and microscopical examinations of the vomitus be neglected.

V. Differentiation from Gastro-succorrhœa: Mistakes should never arise in the continuous form (Reichmann[44]) of this affection; the history at once clears up the case. These patients suffer constantly day and night from stomach symptoms (rapacious appetite, especially for meat, pains most marked during the height of digestion but occurring also at night, excessive thirst, constipation, etc.). Symptoms like these always indicate increased secretory function of the stomach.

When gastric crises are the only symptoms of tabes present, and the vomitus contains large quantities of HCl, we might be tempted to think of the intermittent form of gastro-succorrhœa ("gastroxynsis"—Rossbach[45]). In a case which we observe for the first time and in which large amounts of HCl are present, it would be impossible to make a differential diagnosis, for not only is the clinical picture of both conditions, when fully developed, the same, but the prodromes (headache, fatigue, nausea, anorexia, etc.) are so likewise. The further history of the case must clear up the diagnosis, for tabetic crises are not at all influenced in their recurrence by treatment; the chemical qualities of the vomitus vary from attack to attack, and ultimately other symptoms of tabes develop. In the absence of an opportunity to examine the vomitus, we might draw valuable conclusions from what the patient tells us regarding its taste—if bitter, tasteless, or, as always in gastroxynsis, very sour.

VI. Differentiation from Cholelithiasis: The symptoms of a typical attack of gall stones are so well defined that there is scarcely any possibility of confounding it with gastric crisis. Mistakes may arise in atypical attacks, *i.e.*, those unaccompanied by icterus. This latter symptom is frequently absent in gall-stone colics, and the pains do not always manifest themselves in a typical manner. The pains of gall stones, like those of gastric crises, may also be localized in the epigastrium. Starting from this region or from the right hypochondrium, they may radiate toward the back or toward the right shoulder. They never, however, encircle the body as a girdle, nor do they arise in the iliac region to extend upward into the abdomen. Furthermore, the initial chill, the fever, and the frequently swollen spleen, so common to gall-stone attacks, are absent in gastric crisis. Examination of the liver itself is here a great aid to a correct diagnosis. The entire organ, or more frequently its right lobe, is swollen and tender during and after a gall-stone colic, and we usually find a much enlarged and very sensitive gall bladder as well. In the absence of this last symptom, the eliciting of pain by pressure upward behind the ribs in the region of the gall bladder is a sign of no little diagnostic value (Adler[46]). Boas'[47] "pressure-points," two to three fingers' breadth to the right of the spinal column at the level of the twelfth dorsal vertebra, may aid us in doubtful cases. The examination of the fæces, which should never be neglected in a supposed case of gall-stone colic, may be the only means of clearing up all doubt. Even if we should not find gall stones in the fæces, our suspicion of a gall-stone colic will be very much strengthened by a clay-colored appearance of the stools.

VII. Differentiation from attacks of vomiting and from gastralgias of functional (nervous) origin (hysterical, neurasthenical, and reflex): These attacks have much in common with the gastric crises of tabes, and here, as in the latter, the positive diagnosis requires

recognition of the underlying disease (hysteria, neurasthenia, and disease of other organs). The general characteristics of gastric crises, as already enumerated, may frequently guide us.

I wish to point out a few of the special features of hysterical vomiting and gastralgias, for these are more frequently mistaken for gastric crises than the other types of functional nervous attacks. Those which distinguish an hysterical attack from all others are: the extreme ease with which the vomiting occurs, frequently without any nausea; the striking influence of external conditions (*e.g.*, surroundings, excitement, personal danger, etc ) upon the course of the attack; the capriciousness with which some things are at times vomited, and at other times retained; and the marked contrast between obstinate vomiting and a good appetite. Furthermore, the attack is very liable to cease suddenly, and be succeeded by some other hysterical condition, *e.g.*, singultus, attacks of crying and laughing, dyspnœa without circulatory disturbances, paralysis, contractures, amaurosis, etc. All of these symptoms are in marked contrast with those of tabetic crises.

VIII. Differentiation from Cerebral Vomiting: I leave out of consideration those mixed forms in which tabes is complicated by cerebral and spinal processes, such as dementia paralytica, syphilis, multiple sclerosis, tumors, etc., for then the vomiting is seldom of a pure type. Purely cerebral vomiting resembles tabetic crises in so far as it occurs periodically, quite independently of food ingestion, and at any hour, and may continue day and night. Moreover, if no acute inflammatory processes be present, chills and fever are absent; furthermore, neither in the local condition of the stomach itself, nor in the character of the vomited matter do we find any specific diagnostic signs; and finally, cerebral vomiting is characterized by spontaneous cessation, followed, as a rule, by rapid convalescence and a period of freedom from all digestive disturbances. The points of differentiation are as follows: cerebral vomiting occurs more spontaneously, is seldom preceded by persistent nausea, is usually projectile in character and occurs with the greatest facility; while the vomiting of tabetic crises is seldom spontaneous, is usually forced, being produced artificially (irritation of the pharynx, drinking of large quantities of fluid, etc.), and is preceded by nausea, eructations, salivation, and much retching. Besides this, we find that cerebral vomiting occurs during unconsciousness, and is influenced by positions of the body (*e.g.*, raising of the head), while gastric crises are uninfluenced by this latter condition, and cease with unconsciousness. The boat-shaped abdomen is typical of cerebral vomiting; in tabetic crises the condition of the abdomen follows no rule—it may be drawn in, flat, or protruding. In cerebral conditions, the pulse is slow and frequently irregular; in gastric crises it is rapid, and, when unaccompanied by cardiac conditions, is regular. Finally, it is important to remember that gastric crises may constitute the only symptom of locomotor ataxia, whereas vomiting in cerebral conditions never occurs without other central symptoms.

IX. Differentiation from Uræmic Vomiting: Although acute uræmia is accompanied by uncontrollable vomiting, the entire clinical picture differs so markedly from that of tabetic gastric crises that the two conditons cannot well be confounded. It is quite different, however, with the chronic form of uræmia. Here we usually see the patient for the first time during a severe attack of vomiting, and chronic nephritis is not suspected. Special attention should be given to the previous existence of headaches, unaccountable attacks of dyspnœa with anxiety, symptoms of numbness and uneasiness, especially at night, and contractions of the face muscles and of the smaller muscles of the extremities (Strümpell[47]). The vomiting attacks have much in common with gastric crises: thus, sudden onset without explainable cause; independence of quality and quantity of food, as well as of the time of its ingestion; absence of initial and other chills; frequently no fever; diminution in quantity of urine; absence of local stomach symptoms; continuance of symptoms day and night, and spontaneous cessation. They differ, however, from gastric crises, in that the vomitus contains specific diagnostic characters, namely, carbonate of ammonia as well as unaltered urea (Strümpell[49]). The pulse is small, and in the majority of instances slow. The urine always contains albumin and casts. In addition we find pathological changes in the fundus of the eye.

**Prognosis.**—It is remarkable in what a comparatively short time the patients convalesce when the attacks do not follow each other frequently. Although we can find no record of a fatal termination of the attacks *per se*, still we can easily conceive that patients otherwise enfeebled should be further weakened by frequent and intense crises, until they ultimately die of asthenia or fall victims to phthisis. A large number of cases with the latter termination have been reported. When complicated with laryngeal crises the patients may die of asphyxia during such a laryngeal attack.

Gastric crises admit of no prognosis in regard to duration and frequency. Reports of complete cessation of the attacks are extremely rare. Von Leyden[6] declared he had seen two such cases. To this I can add two cases in which there have been no attacks for over three years. In this connection I would like to discuss the conclusion arrived at by Benedict in 1882 and 1887[90] and which I cannot find elsewhere quoted. He states that next to cases of locomotor ataxia with initial optic atrophy, those with initial gastric crises offer the best prognosis. He has seen the ataxic symptoms disappear in two-thirds of the latter class of cases which came under his treatment.

Unfortunately the extent of the tabes in our own cases was not sufficiently noted at the time of first observation; hence I can only report in this connection from my own personal notes. Briefly stated, of our twenty-five cases of from two to ten years' duration, fifteen with gastric crises as the initial symptom are still in the pre-ataxic stage of the disease. In five, Westphal's and Romberg's symptoms are absent; in four others Westphal's only is absent, while Romberg's is but slightly indicated. The remaining ten cases present complete symptoms of tabes; in nine of these the other tabetic symptoms developed later than the gastric crises; in one they occurred prior to the crises. Thus we find an apparent confirmation of Benedict's observation in our own cases; *i.e.*, two-thirds with gastric crises as initial symptoms are still in the pre-ataxic stage. Whether or not symptoms of tabes had ever been present and retrograded, I cannot now state.

Here I would again refer to the case mentioned by Gowers,[91] which was still in the first stage of tabes after eighteen years of gastric crises.

**Treatment.**—Treatment must be directed against two conditions, the attacks themselves and the intervening periods. During the attacks themselves, it must be our aim to give the patients relief from their great suffering, and in the protracted cases to provide for sufficient nutrition. The one sovereign remedy which answers the first of these indications is hypodermic injections of morphine. Such injections possess the advantages of easy administration and of rapid and, in the majority of cases, certain action. But they also have the great disadvantage, especially in chronic cases, of inducing morphinism and of necessitating

ever-increasing doses. The immediate administration of morphine is justifiable in the very severe cases, but by no means in mild ones. The list of remedies tried as a substitute for morphine is legion; it is useless to repeat them all here. A striking example is furnished us in the written communication of a patient, who has suffered for nine years from these gastric attacks. He says that the following remedies have been tried: change of climate, mineral springs and baths, cold packs, hot and cold douches, frictions, massage, electricity, divers teas, liquors, powders, pills, and plasters, morphine and opium suppositories, hypnotism, suggestion, "electro-homœopathy," vegetarianism, and the rest cure.

Recently Ostankow[51] reported surprisingly successful results from oxalate of cerium. Dr. Boas, having obtained good results with this remedy in a few cases which he himself had observed, and being desirous of further experiences, asked me to try it in our cases.

The remedy was given in eighteen cases. Treatment was begun as early as possible during the attack, the dose being 0.1 gm. (gr. iss.) every two to four hours according to the severity of the symptoms and the effect obtained. The remedy was continued between the attacks in doses of 0.06–0.1 gm. (gr. i.–iss.) three times a day. From the results obtained, I am led to conclude that oxalate of cerium has no influence whatever upon the pain, and is indicated to relieve nausea and vomiting.

The effect of two other remedies, antipyrin and nitrate of strychnine, was also studied. The employment of antipyrin in these attacks is not new (*cf.* Gowers,[31] Zippert,[52] etc.). Its great solubility in water renders it especially applicable. It was given in doses of 0.25 gm. (gr. iv.) repeated hourly. If the desired effect was not obtained in four hours, the dose was increased to 0.5 or even 1.0 gm. hourly (gr. viiss.–xv.), the effect upon the heart being carefully observed. Though given in all to eleven patients at various times, no disturbance of the circulation was observed. From the results obtained from antipyrin, I believe that it has no influence upon the vomiting *per se*, but at times acts as a general sedative, relieving those cases especially in which pain forms the most prominent symptom.

Nitrate of strychnine, given at the suggestion of Professor Oppenheim, was employed in doses of 0.002 gm. subcutaneously (gr. $\frac{1}{30}$). It was administered during five attacks only, in which both oxalate of cerium and antipyrin had been of no benefit whatever. In three cases there was no relief at all; in two others relief was almost immediate, the patients falling asleep soon after the injection, and awakening entirely free from symptoms. In one of these two cases this beneficial effect was obtained during two separate attacks.

The results derived from the employment of these three remedies will be best seen from the following summary:

| | Number of Crises | Symptoms Entirely Relieved. | Symptoms Partially Relieved. | Symptoms Not at All Relieved. |
|---|---|---|---|---|
| Oxalate of cerium .. | 18 | 2 | 3 | 13 |
| Antipyrin..... | 11 | 0 | 5 | 6 |
| Strychnine nitrate.. | 5 | 1 | 1 | 3 |

At the first glance these results may not appear very promising, but if we remember that, of all the other remedies heretofore employed, morphine (or opium) is the only one from which the patients derive more than temporary relief, I feel justified in believing that these three remedies will prove an important addition to the treatment.

The second indication, viz., providing for sufficient nourishment during an attack, may become a very earnest question. If the general nutrition is good and the attacks are short, it will scarcely have to be considered, for here it is best to withhold all food for the time being. The question becomes quite a different one, however, if the attacks are severe and protracted, especially if the patients are poorly nourished. Rest is the first indication in all seriously disturbed functions of an organ. But, since total abstinence will cause more harm than good in these severe protracted cases, we must employ all possible means to provide the patients with nourishment during an attack. While the symptoms are very acute it would be best to restrict our patients to fluid diet, beginning with teaspoon doses, half-hourly or hourly. The indication for the fluid diet is a threefold one: to relieve nausea and pain, to quench the intense thirst, and to give nutrition. There are a number of liquids which fulfil these three indications. To mention a few, we have black coffee, cognac, champagne, tea, lemonade, milk, koumiss, matzoon, also cloths saturated with ice-water placed over the mouth, cognac with cracked ice, etc. In this connection I might mention that a few drops of cocaine solution placed upon the tongue frequently relieve thirst and vomiting. The old remedy of a drop of tincture of iodine in a teaspoon of water, repeated hourly, may also be tried.

Where pain is the most distressing symptom it is better to give the fluids hot rather than cold. Boas[53] has suggested the employment of a morphine injection to permit of ingestion of food in the severer cases. I have seen this same result accomplished, however, by a suppository of opium and belladonna.

In very prolonged and severe cases we shall hardly succeed without rectal alimentation. This serves the purpose not only of supplying nourishment, but also of replacing the great loss in fluids and of relieving thirst. By the addition of alcoholics to the enemata we may stimulate the heart. In those severe cases which do not yield even to morphine, and in which, in spite of rectal alimentation, the condition of the patient becomes a most serious one, I believe the subcutaneous injections of oil, as suggested by v. Leube[54] in extreme inanition, would be in place. The technique is very simple; the danger, if carried out under proper aseptic precautions, is *nil*. Strauss[54] has constructed and described a very commendable apparatus for this purpose.

If no organic disease of the stomach be present, convalescence is marked by a very strong appetite, and the patients, if left to themselves, would frequently over-eat. In a paper read before the Hufeland Gesellschaft, Rosenheim[55] called attention to the occurrence of motor insufficiency of the stomach following the gastric crises of tabes. He had observed two patients himself in whom, after cessation of severe attacks, dyspeptic symptoms (pressure, distress, gnawing pains, etc.) appeared after each meal, and in whom he had found food remnants at the time when the stomach should have been empty. This is a very important observation, and teaches us the necessity of a careful diet during convalescence.

Since the nutrition of our patients is below par, it will be our first duty to increase it. The rules of diet and nutrition for exhaustive conditions occurring in chronic disease apply with full force to the convalescent state of gastric crisis. We begin with easily digested food, and as the general condition and especially that of the digestive organs permits, we increase as rapidly as possible to a more liberal diet. Our aim is always the combination of greatest digestibility with the highest amount of nourishment, and it is best not to limit the patients too much in the selection of food. At first food in fluid or semifluid form should be allowed, solids being withheld until all danger of motor weakness is past. Above all, fluids of slight

nutritive value are to be avoided, for these serve mainly as a cumbersome (or harmful) ballast to the stomach. During the first days of convalescence, milk, whenever well borne, should constitute the main article of diet. It should be tried at first in its natural form, preferably boiled. The addition of a little lime water will be useful if there be secretory or motor disturbances. The quantity of milk given at one time should not exceed one hundred grammes. The addition of a little coffee or of cacao deprived of its fat will sometimes prove a welcome change from milk. For those to whom milk as such is not acceptable, there is a long list of palatable and easily digestible milk preparations. I refer to milk-soups, kefir, koumiss, matzoon, custards, milk-punch, desiccated milk, etc. These preparations are not only in themselves highly nutritious, but also permit of the addition of other articles of food, thus enhancing their caloric value and increasing the dietary list. Such addenda are eggs, butter, sugar, cognac, zwieback, toast, crackers, rice, farina, hominy, corn starch, arrow root, and the like. Next in value to milk in the diet of early convalescence are eggs. These, too, admit of many modifications in their preparation.

Gradually we increase the diet list, during the first few weeks allowing the starchy carbohydrates (those comparatively poor in cellulose), *e.g.*, young carrots, cauliflower tops, and young spinach, all in mashed form, mashed potatoes with milk, and besides these butter, good meat broth with egg, finely minced or scraped beef, ham, white meat of chicken, young pigeon, sweetbread, calves' brains, boiled lean fish, jellies, apple sauce, and other compots not rich in cellulose. Caviar, a sardelle or two, ham, and some compots stimulate the appetite and are usually acceptable to the patient.

If food in its natural form is sufficiently partaken of, there is no reason to resort to artificial food preparations, since these latter are less nutritive and more expensive. They are useful, however, when the appetite is very poor, and too little natural food is partaken of. Owing to the high amount of extractives and salts contained in them, meat-juice preparations are useful to excite appetite. The cheaper food preparations, eucasin, nutrose, tropon, the various meat and vegetable powders, are especially valuable as additions to natural food preparations. In passing I would remark that home-made beef broths and beef teas accomplish the same purpose as the albuminoid preparations purchasable in the market, and furthermore, that it is easy to make efficient meat and egg powders one's self.

If no organic disease of the digestive organs exist, rapid progress may be made to full diet. Forced feeding—the Weir Mitchell or similar treatment—may accomplish much good if the patient be debilitated in consequence of cibophobia.

Medicinal treatment during convalescence must necessarily be a symptomatic one. The importance of an exact knowledge of the state of the digestive organs, especially as to secretory and motor functions, cannot be too strongly emphasized. It is also very important that the patients enjoy as much bodily and mental rest as possible. If these precautions be carried out, we not infrequently see longer intervals of freedom from attacks.

The general treatment of patients suffering from gastric crises is similar to that of other tabetic patients. Reference to cases published (Hoffmann,[37] Rosenthal,[29] etc.), as well as personal observations, lead me to conclude that anti-syphilitic treatment in cases with a preceding history of specific infection, exercises no beneficial influence whatever either upon the character of the gastric crises or upon the locomotor ataxia itself.

Since we know of no therapeutic measures which will cause either total disappearance of gastric crises or a diminution in their frequency, I would again emphasize that it is of paramount importance to raise and keep the general nutritive standard of these patients as high as possible.

In conclusion, I desire to express my sincere thanks to my former chief, Dr. Boas, as well as to Professor Oppenheim, for the material which they so kindly placed at my disposal, and for their valuable assistance to me during my study of the same.

## VENTRAL FIXATION OF THE ROUND LIGAMENTS FOR RETROVERSION AND PROLAPSUS UTERI.

By A. MONAE LESSER, M.D.,

SURGEON FOR ABDOMINAL DISEASES AT THE RED CROSS HOSPITAL OF NEW YORK.

It is unnecessary at this day to speak of the advantages or disadvantages of utero-ventral fixation, Alexander's, or other operations performed for the purpose of bringing the uterus into its anterior position. When the ligaments are strong and there are no other complications, shortening by traction through the inguinal canal must be acknowledged as the, so to speak, anatomical method, but when the ligaments are thin and weak, and when other complications exist with a retro- or prolapsed position of the uterus, the operation herein described is by far the easier. It can be more quickly performed, in every instance with success, and avoids all the difficulties which may arise through weak ligaments, in Alexander's operation, in utero-ventral or any other fixation. It leaves the uterus in its free position, and neither interferes with its physiological requirement nor changes to any material extent its relations with other organs.

The instruments required for the operation are: scalpel, scissors, a pair of long pincettes, a few artery forceps and small retractors, a long, straight needle with an eye near the point, a curved right-angular needle, and a repositor. The needle is curved at near a right angle, is straight from the point to the curve, and again from the curve to the eye, and can be used for a suture in a straight as well as in a curved direction. The point is sharp and flat, so as to be able to take up a thin, yet broad portion of tissue if required. I have termed it hernia needle, as I designed it for general use in hernial operations. The repositor is made in the form of a heavy uterine sound, and consists of a uterine portion, a vaginal portion, and a handle. The uterine portion is 5 cm. in length, and stands at an angle of about 105° with the vaginal portion. At the angle is a small shoulder about 2 cm. in diameter for the support of the uterus when held in position, making the piercing of a soft fundus impossible. The vaginal portion is slightly curved, and the handle stands at an angle with the vaginal portion. When the repositor is in the uterus and in proper position, the handle must be long enough to stand horizontally above the field of operation, to be manipulated by the operator or assistant without needing to put his fingers into the vagina.

The procedure for the operation is as follows: The patient is prepared for cœliotomy. If curettage is necessary it should, of course, be done first. The repositor is placed in the uterus, with its handle standing horizontally. After the operative field is made aseptic and proper dressing placed around it, an incision is made transversely from about 2 cm. inward of the point anatomically denoting the internal abdominal ring on one side, to the same point on the other side and about 2.5 cm. above the pubis. The incision is made through the skin and fascia, down to the aponeurosis of the external oblique; it should not be made funnel-shape and not higher up than stated. The integument is then drawn upward and downward, respectively, in order to lay the parts free for the second incision.

From this point I proceed differently in the various cases. The simplest method of all is the median incision, particularly so when there are adhesions or other internal encumbrances. In the latter case the incision has to be made of sufficient length to permit the necessary manipulations for correction. If there are no complications beyond the direct object of the operation, a short longitudinal opening is made through the linea alba and peritoneum. The uterus is then placed in position by means of the repositor, and the position of the ligaments and surroundings ascertained. A silkworm or kangaroo suture is then inserted with the hernia needle about 0.5 cm. inward from the outer angle of the incised skin, and passed horizontally, not through the skin, but through muscle, fascia, and peritoneum. While the outer end of the suture is held with forceps, the inner serves to indicate the place to which the ligaments should be attached. If the uterus is held in normal position with the repositor, the ligament can be picked up with pincettes almost opposite the suture, but before the needle is carried under it the exact place for the attachment should be measured. The needle is then carried under and around the round ligament at the required place, necessarily taking along the broad ligament covering it. The thread should be long enough to allow the suturing while the ligament is relaxed again.

The hernia needle is removed, and the eye-point needle is passed parallel with, but 1 cm. below, the place of entrance of the first or descending suture. The eye needle is then threaded with the ascending strand of the suture, which is drawn up and out of the abdomen, and held there with forceps (after a little practice all can be done with the hernia needle alone). A second suture is made through the abdomen and ligament in the same manner as the first and about 0.75 to 0.85 cm. inward from it. This may be done without measurement, but the distance between the sutures outside must be as nearly as possible the same as that between the sutures in the ligaments; a third suture is passed at the same distance from the second, giving in all an attachment of about 1.5 to 2 cm. The ends of the sutures should be held outside with forceps, and not be tied immediately, so that the ligament may remain relaxed, to serve as a comparative landmark for the other side.

While working on one side, I usually keep the other incised parts covered with a warm pad, and after changing the pad the opposite side is attended to in the same manner as the first.

When all the sutures are in and before the ligaments are drawn up to be tied, I abrade the portion of the ligament and peritoneum (by scraping with the scalpel or curette) along between the sutures, so that a union may readily take place and become more firm. After this the sutures on either side, beginning with the most outward one, are drawn up closely and tied firmly, but not too rigidly. The ends are cut short and buried under the skin and fascia, which are then closed, preferably by subcutaneous suture.

I prefer the transverse section of the skin, as it has many advantages: first, it permits the insertion and burying of the sutures without the necessity of detaching the skin from the large area; second, it opens a clear field of the abdominal muscles and fascia, and is a guide for the insertion of the sutures; and third, it gives a better union on account of the oblique and transverse vascular and nerve supply of the skin. The only vessel which may appear in the field of the skin and fascia incision is the superficial epigastric or several of its branches, which with care need not be incised, but may also be ligated. Some care is required not to go too close to the internal abdominal

ring, the needle for the most outward suture being inserted through muscle, fascia, and peritoneum, in order not to pierce the deep epigastric artery, the course of which, although quite close to the ring, sometimes in its upward course deviates a centimetre or two inwardly. It must also be considered that the measurements, although taken from average cases and cadavers, vary somewhat in different cases. But the points required can be readily recognized when the muscles and aponeurosis are laid free after the transverse incision of the integument. It is best to hold a small pad on forceps against the parietal peritoneum while a needle is passed through it.

If the operation is performed in Trendelenburg's position, and there are no adhesions or other previously existing complications, handling the tissues with the fingers directly is not necessary, all manipulations being better performed with the aid of necessary instruments, although, if any doubt exists in regard to the course of the deep epigastric, one finger would better be placed in the abdomen and pressed against the anterior wall in order to feel the beat of the vessels and be guided by it.

There are several other methods of procedure after the transverse incision through the skin and fascia has been made. They offer, however, little advantage and require some practice. Thus, for instance, I have made a small transverse incision through the aponeurosis of the external oblique, and separated the fibres of the internal and the transversalis in the same direction at the point mentioned above for the sutures. The object was to find out which of the operations could be performed most quickly and be of the greatest advantage. The deep fascia and the peritoneum in some places may also be cut transversely, but always with care, when near the inner boundary of the internal abdominal ring, in order to avoid the possibility of cutting through the deep epigastric vessels and other vascular supply, which in some cases may cause annoyance if carelessly incised.

After being assured that there is no encumbrance between the incision and the ligament external to it, the ligament is picked up with pincettes, the external portion (toward the ring) drawn up tightly, and the portion toward the uterus drawn up in accordance with its length and requirement. The ligament is then sewed up between the fibres of the two inner abdominal muscles, the needle being carried from above the incision through the internal oblique, transversalis, fascia, peritoneum, ligament, and back through the tissues below the incision. The aponeurosis of the external oblique is sewed over it, and the other side attended to in the same manner. When the operation is completed the skin and fascia are closed as before.

If the operation is performed with strict asepsis the patient is able to rise on the twelfth day, or perhaps before. Hernia could be the result only of errors in asepsis, or the course of the incision through the muscles. It must be remembered that at the point mentioned almost all the fibres and aponeuroses of the broad abdominal muscles run more or less in a transverse direction, although they are frequently pictured differently. In two of my cases, one by lateral and the other by central incision, pregnancy followed four and a half and six months respectively after the operation, without complications, and was carried to full term, the uterus remaining in its anatomical position after normal delivery.

I had never seen this operation performed, but the suggestion of attaching the round ligaments, instead of the fundus uteri, was made to me some years ago by Dr. T. Gaillard Thomas, and through an accident in which a very thin ligament tore during the progress of an Alexander operation I remembered the suggestion and proceeded with an incision through the internal ring. The recovery was so rapid and satisfactory that in most instances I have preferred the ventral fixation of the round ligaments to other operations performed for similar purposes, particularly so in cases in which Alexander's operation was not advisable.

## AN INTERESTING CASE OF HYDROCEPHALUS WITH PSEUDO-SPASTIC SPINAL PARALYSIS.

By FREDERICK STRANGE KOLLE, M.D.

BROOKLYN,

EX-INTERNE TO KINGS COUNTY HOSPITAL, NEW YORK.

The patient, Edith R——, now twenty-one years of age, was born in Hartford, Conn. The mother gives the following intelligent history of the case: that she has always been quite well herself, being, however, of an extremely nervous temperament; that she had a miscarriage of twins prior to the pregnancy with this child. When twenty years old she was confined by Dr. H——. The labor was normal and the presentation of the fœtal ovoid was cephalic. She noticed nothing abnormal with the child until the third month, when the infant was suddenly taken ill with the following symptoms: convulsions, fever, oscillation of the eyeballs, throwing back of the head, marked tympanites of the abdomen, and persistent crying. Doctor R—— attended the patient, and after twenty-seven hours' duration of the above symptoms, the child gradually recovered, except that the head began to increase in size. The infant was unable to use its lower extremities until the fifth year, despite its good development and nourishment. When eleven years old it acted like an idiot—laughing and crying alternately. Drs. F—— and L——, of Brooklyn, then saw the patient and applied a band of some material around the head, which had to be removed, as it caused stumbling and falling when the patient tried to stand or walk.

The patient presented herself at the hospital in 1893, and the following history was obtained: Head very much enlarged; height of body five feet one and three-fourths inches; weight one hundred and thirty-eight pounds; body symmetrically developed and well-nourished; appetite good, bowels regular, tongue uncoated; pulse 74; temperature in axilla 98.4° F.; condition of blood-vessels soft, compressible, and well filled; digestion good; liver outline, upon percussion, normal; heart sounds and chest normal. The reflexes of the lower extremities were markedly exaggerated; sensation was normal throughout. A spastic disturbance is observed in the gait of the patient with an uncertainty of equilibrium, the step being of a spastic type—the heel coming down suddenly and heavily on the floor. Muscular reaction of the lower extremities is normal to the primary or secondary direct or indirect faradic current. After careful study and investigation I concluded that this spastic condition was due chiefly to the hydrocephalic fluid gently compressing the lateral columns of the spinal cord in the cervical and lumbar regions, there being either a hydro-myelus, or syringo-myelus, or both, present. Shulz says: "Symptoms of almost the entire and pure type of spastic spinal paralysis were shown in a case, the autopsy on which disclosed a hydro-myelus with coexisting degeneration of the lateral columns."

It is clearly shown by the symptoms of this case that there is muscular irritation. I do not believe there is any degeneration in the lateral columns of the spinal cord, but think the symptoms are purely due to the cause mentioned. The reason that we do not have the same symptoms in the arms may be explained on the assumption that gravity may have something to do with

it, allowing the fluid to go to the most dependent portions. Strümpell says that "there are disturbances of mobility in the upper extremities also," but they are not present in this case. The exaggerated reflexes, with the spastic movements of the voluntary muscles and a limitation of the symptoms mostly to the motor sphere, lead me to call this case one of pseudo-spinal paralysis, dependent upon either hydro-myelus or syringo-myelus, or both, due to the pre-existing chronic hydrocephalus. Spastic movements are described by Shulz, Wood, Gowers, Aitken, Osler, Strümpell, Mills, and others, but I have failed to find any extensive articles on this subject. I introduce this case as one of great interest, especially to those interested in hydrocephalus. The patient is well educated, has a clear soprano voice, is of pleasant disposition, and has a fair penmanship. The measurements of her head are as follows, as compared with Dr. Frederick Peterson's measurements of the normal female cranium:

| | Average of Normal Female Skull. | Skull of E. R—. |
|---|---|---|
| Horizontal circumference | 50.0 cm. | 68.4. cm. |
| Anterior demi-circumference | .... | 38.5 |
| Posterior demi-circumference | .... | 30.1 |
| Naso-occipital arc | 31.0 | 46.2 |
| Binauricular arc | 31.0 | 41.9 |
| Antero-posterior diameter | 17.2 | 22.2 |
| Greatest transverse diameter | 14.0 | 19.5 |
| Binauricular diameter | 11.9 | 16.1 |
| Bizygomatic diameter | .... | 13.9 |
| Volume | 1,300 | 1,846.81 |
| Facial length | 12.37 | 12.37 |
| Length-breadth index | 83.8 | 87.8+ |

Type of skull, brachycephalic. Profile line (Kirchoff), orthognathous.

The cranial bones of the skull are entirely ossified, the sutures firm, etc. This head, as compared to other recorded cases, is an exceedingly interesting one. Cardinal, of the London Hospital, who died in his twentieth year in Guy's Hospital, had a head circumference of 33½ inches, and according to other authorities 32¼ inches. A head in the Cruikshank Museum measures 51 inches; another, in the Warren Museum, 27½ inches. The cranial bones of Cardinal were exceedingly thin and almost translucent. In Aitken's case of a child, whose head measured 29 inches in circumference, the child died early in life. Dr. Bondurant, of Alabama, mentions a case of a man (B. M. A.), whose head measured 29 inches, dying in his forty-eighth year, but who was much demented or idiotic from infancy. Other remarkable cases have been reported occasionally, measuring as high as 80 cm., but almost all died before, or became idiotic, melancholic, or insane after, puberty. Strümpell says that such persons living after five years of age are striking exceptions, and that the possibility of recovery has not been demonstrated. Mills says that "cases have been reported of even exceptional brightness, but that the development of the body is retarded and imperfect, few reaching an average mental capacity.

On June 16, 1893, Dr. W. B——, of Brooklyn, inserted an aspirating needle between the third and fourth dorsal vertebræ and through the membranes of the cord, succeeding in drawing off about one and one-half ounces of a clear, sparkling fluid, having the consistency and the light-refractive property of high-grade glycerin.

Prof. G. H. Bartley kindly made an analysis of the fluid for me with the following result: Quantity, 3.12; color, clear; odor, none; sediment, none; reaction, faintly alkaline; specific gravity, 1007.7; albumin, very slight trace. A precipitate is obtained by the addition of nitric acid, which is redissolved by heating, returning again on cooling. The proteids are also precipitated by the addition of a saturated solution of magnesium sulphate. Upon the addition of Fehling's solution to the fluid a light brownish-red precipitate is formed. The following analysis confirms the fact that the fluid drawn from the spinal column was hydrocephalic and of chronic nature. The wound caused by the aspirating needle healed readily under antiseptic dressings. The patient, however, showed little if any noticeable improvement in her walk. It may have been that all the fluid external to the cord was not drawn off, because of the bent condition of the body, necessary to facilitate the introduction of the needle, thus impeding the removal of the fluid because of unequal pressure exerted about the cord, or that the cord, having been in a compressed state for years due to the presence of the fluid, failed to respond to the space produced by the drawing off of the myelitic fluid, and allowed the same to fill up again. I agree that this is an exceptional case, and do not doubt that it will continue for years *in statu quo*, and that the patient will enjoy good health for such time. The disturbance in her gait has been much worse than now, and at present causes but little difficulty.

The above paper was written over six years ago, and, although of great interest, was never forwarded to the medical press; in fact it might never have been published had not the patient communicated with me quite recently. Although I did not see the patient personally, I learned she was feeling very well, had been able to work for the last four and one-half years, and that gradually after the operation the spastic condition in her limbs had improved but never entirely disappeared. She was employed as a waitress in a country hotel at the time of sending me these facts. These later developments increased my personal interest in the case. This accounts for the late publication of the data.

2 Willow Street.

## Progress of Medical Science.

**Splenectomy for Floating Spleen with Twisted Pedicle.**—In the *Annals of Surgery*, vol. xxx., No. 3, 1899, Stone reports the case of an unmarried woman, thirty-five years old, with unilateral salpingo-oöphoritis, who presented what was thought to be a pelvic tumor, but which proved on operation to be a floating spleen, not greatly, if at all, enlarged. The operation was undertaken for the relief of menorrhagia and dysmenorrhœa, and the spleen was mistaken for a subperitonal fibroid. As the displaced spleen had not caused constitutional, or indeed any, symptoms, it was thought best not to subject the patient to an additional operation of considerable danger, and, accordingly, the spleen was allowed to remain. So far as the patient's symptoms were concerned, she had complete relief from her former troubles, and remained well for six years. At the end of this time she was suffering from acute pain extending over the left side and lower half of the abdomen. The abdomen was exquisitely tender to touch, and it was not difficult to find the tumor, whose most prominent portion presented to the left side and rather below the umbilicus. Owing to the very great sensitiveness and nervousness of the patient, it was difficult to make a careful study of the situation and of the relations of the tumor to other organs. The patient presented the symptoms usually observed in patients having an ovarian cyst with a twisted pedicle. Her pulse was quick, and her temperature rose in the evening to 102° F. The tumor was easily decided to be the spleen, and

the sudden onset of pain and the fever were attributed to a possible inflammation of the organ. After careful consideration splenectomy was undertaken. The abdomen was opened in the median line over the middle third. A dark tumor at once presented, which was enveloped by the omentum and the intestines for the most part, although there were some adhesions to the abdominal parietes. After removal of the omentum it was not difficult to remove the spleen, which was greatly enlarged, quite soft, and of very dark color in part, due to extravasation of blood, and was adherent throughout its entire surface. The mesentery in this case was very long, and the spleen was rotated six times on its axis. The twisting of the pedicle served somewhat to shorten its length, and hence the spleen was elevated from the pelvis, its former abode, to the position described. The veins of the mesentery were very large, in consequence of extreme distention from stasis, and they were filled with blood-clot. This clot was so extensive as to cause anxiety lest it prove a hindrance to recovery. The greatly distended vessels could be felt as far as the hand could reach under the stomach and along the course of the vessels supplying the stomach, the pancreas, and the spleen. No unusual symptoms, however, appeared to prevent the patient's recovery, which seemed beyond question five weeks after the operation. The specimen weighed almost five pounds.

**The Treatment of Exophthalmic Goitre with Bile Administered by the Mouth and by Hypodermic and Intrathyroid Injection.**—Allan reports in *The Lancet*, August 26, 1899, the case of a tall, sallow, and nervous married woman, fifty years old, who had for ten years been subject to occasional attacks of what was believed to be exophthalmic goitre, but whose thyroid gland was never sufficiently enlarged to be noticeable except on examination. On the second day of an attack of influenza acute enlargement of the thyroid gland was noticed, the pulse rate being 160. For several days dyspnœa, almost incessant cough, great nervousness, diarrhœa, vomiting, and delirium, with a temperature varying from 104° F. downward, were among the most prominent symptoms. The symptoms varied from day to day, and finally exophthalmos and Stellwag's and Graefe's signs appeared, with pigmentation around the eyes. Paretic dilatation of the abdominal aorta was also very persistent. A peculiar feature was an absence of bile from the dejecta and an abundance of pale urine, notwithstanding the sweating, which was mostly unilateral. Upon the assumption of a paresis of the secretory function of the liver-cell, sodium salicylate and sodium phosphate were administered, but, failing to influence the secretion of bile, bile itself was given, and with almost direct benefit, especially with regard to the diarrhœa and the vomiting. The equivalent of from 1,500 to 2,250 grains was administered daily. After the third week administration by the mouth was supplemented by hypodermic injection, the equivalent of 360 grains of bile being injected between the shoulder blades. Intense reaction followed, but the untoward symptoms were relieved by the administration of antipyrin. The equivalent of 120 grains of bile was now injected twice daily, the amount being gradually increased to 360 grains twice daily, and being given with 15 grains of antipyrin in whiskey and soda. Some of the injections were made directly into the thyroid gland. The improvement that followed was so satisfactory that after some time only 120 grains were administered twice weekly by the mouth, and this was continued for three months. At the end of six months the patient had gained twenty-eight pounds in weight and expressed herself as feeling better than she had in twenty years. Of the more persistent symptoms, the exophthalmos disappeared quite unnoticed, then the tachycardia, and then the tremors. The thyroid enlargement subsided slowly. Many weeks elapsed before bile appeared in the dejecta.

**Total Laryngectomy for Epithelioma.**—At a recent meeting of the New York Surgical Society Dr. Brewer (*Annals of Surgery*, vol. xxx., No. 3) reported the case of a woman who nine months previously had noticed gradually increasing hoarseness, with spasmodic irritating cough. Examination disclosed the presence of a small growth just above the anterior commissure of the vocal bands, which, after a certain amount of preliminary treatment, was completely removed. The patient was entirely relieved as the result of the operation, and remained well for two or three months. Later, however, the symptoms returned, and they increased rapidly. On examination by competent pathologists the original growth proved to be an epithelioma. When examined again the laryngeal growth presented the appearance of a typical papilloma. It was about the size of a small pea, was situated in the anterior angle formed by the vocal bands, and was not associated with any thickening or evidence of infiltration of the surrounding tissues. Operation having been decided upon, after preliminary tracheotomy an incision was made into the larynx, extending from the hyoid bone to the first ring of the trachea. The growth was removed, together with the vocal bands and the anterior third of each thyroid cartilage. The wounds were packed, and the patient made a satisfactory recovery, being dismissed after the lapse of fourteen days. She remained well for about two months, when the growth reappeared, and it now increased with great rapidity, in about six weeks from its first appearance nearly filling the cavity of the larynx, and rendering breathing difficult. Operation was again undertaken, an incision being made under chloroform anæsthesia in the median line from the body of the hyoid bone to the suprasternal notch. The trachea was opened below the isthmus of the thyroid gland, the upper segment of the tube plugged with sponge, and the cannula introduced. From the upper extremity of the incision two additional incisions were made extending obliquely upward toward the angles of the jaw. The two superior thyroid arteries were found and ligated, and, although no enlarged glands were discovered, the areolar tissue surrounding the vessel was removed. The larynx and the upper part of the trachea were then cleaned and separated from their muscular attachments. The trachea was divided, and the posterior surface of the thyroid cartilage carefully dissected from the œsophagus. The pharynx was not opened until the larynx had been entirely freed from its attachment to all surrounding structures. The two were then separated, the resulting pharyngeal wound completely united with catgut, the trachea sutured to the skin, and the incision partly closed and packed. During the next ten days gauze pads soaked in hot boric-acid solution were kept constantly over the opening of the tracheal tube. The wound was dressed frequently and healed promptly. The patient swallowed water on the second day, and took milk and other liquid food freely after the third day. On the tenth day, as the result of a violent attack of coughing a small leak occurred in the pharyngeal wound. This healed spontaneously, and caused the patient no inconvenience. She sat up on the fifteenth day, and was thereafter well.

**Hæmaturia Attending Tuberculosis of the Kidney.**—Newman (*Lancet*, August 26, 1899) points out that hemorrhage from the kidney occurs: (1) in consequence of injury, independently of any pre-existing tuberculous lesion, the effused blood or injured tis-

sues forming a nidus for tuberculous infection; (2) as a premonitory symptom of tuberculous disease long antecedent to the development of a gross renal lesion; and (3) in consequence of destructive tuberculous processes in the pelvis or the parenchyma of the kidney. He reports cases illustrative of each of these varieties of hæmaturia. The following method for detecting tubercle bacilli in suspected urine is recommended: A quantity of urine is permitted to stand in a conical glass in a cold place for not more than six hours, and from the deposit a small quantity of débris is selected and placed in a glass of 0.75 per cent. salt solution. The deposit is, however, obtained more rapidly and more reliably by centrifugation, which should always be resorted to when the number of bacilli is supposed to be small or when the urine contains much mucus or blood. When the mucus is considerable it may be necessary first to render the urine slightly alkaline. A small amount of the sediment is placed on a cover slip and spread in a thin layer by pressure through a second cover slip. The slips are dried in the air, and they may be more firmly fixed over a spirit lamp or in front of a fire. They are then placed in, or floated, face downward, upon a solution of aniline magenta or of gentian violet. Decolorization is effected by passing the cover slip through a twenty-five-per-cent. solution of nitric acid, and then washing in water. Tubercle bacilli are cultivable from urine only with difficulty. Their presence may further be demonstrated by animal inoculation. When the existence of tuberculosis has been demonstrated it is important to determine whether one or both kidneys are affected. This may be done by catheterization of each ureter separately, and an individual study of the secretion from the corresponding organ.

**An External Application to Lessen the Dangers from Desquamation in Scarlet Fever.**—To prevent the dissemination of the scales thrown off from the skin in the sequence of scarlet fever, Williams recommends the application of a mixture of one part of glycerin to seven parts of a ten-volume solution of hydrogen dioxide containing a small amount of free hydrochloric acid. It has further been found that if the patient is rubbed all over with a similar solution, but without the hydrochloric acid, the period of desquamation may be materially shortened and removal of the layer of epithelium hastened.—*Boston Medical and Surgical Journal*, September 14, 1899.

**Successful Splenectomy for Rupture.**—Heaton reports the case of a boy, nine years old, who presented symptoms of severe intra-abdominal hemorrhage, probably from rupture of the liver or of the spleen, as a result of being knocked down and run over by a heavy cart. Abdominal section was performed five and a half hours after the accident; a rupture of the spleen was found, and the organ was removed. Recovery ensued without untoward complication. Examination of the blood disclosed the presence of a marked pathological leucocytosis greater than in any case hitherto reported; a proportionate diminution in the number of lymphocytes, notwithstanding the slight hyperplasia of the lymphatic glands; a proportionate and large actual increase in the large mononucleated forms; an abnormal number of the so-called transitional cells, exhibiting changes in their nuclei and protoplasms as in the transformation of large mononucleated cells into finely granular oxyphiles; and a remarkable want of interference with the ordinary red blood cells. Altogether seven cases of splenectomy for rupture have been reported, and a study of these leads to the conclusion that a marked leucocytosis follows removal of the spleen, appearing immediately after the operation and gradually declining, although it exists in less degree for six months or more. The various forms of leucocytes are increased in number in various proportions, and they do not bear the same ratio to each other as in normal blood. The anæmia induced by the accident is but slowly recovered from after the removal of the spleen. In three of the seven cases the removal of the spleen was followed at an interval of from ten days to three weeks by a train of symptoms characterized by pyrexia, wasting, extreme weakness, anæmia, frequent pulse, pallor, thirst, and headache, which last for a varying period, and are slowly recovered from. The external lymphatic glands undergo enlargement, and in some cases a marked hyperplasia.—*British Medical Journal*, August 19, 1899.

**A New Operation for Inguinal Hernia.**—In order to diminish the chances of recurrence, Beck has employed the following modification of the Bassini operation for inguinal hernia: The incision is made down to the internal surface of Poupart's ligament, alongside the outer margin of the rectus muscle, exposing its lower third, down to the shelving portion of Poupart's ligament. The sac is isolated from the cord, and ligated and cut off within the internal ring. While the cord is held away the cut aponeuroses are dissected backward, and an oblique incision is made which divides the lateral fibres of the rectus muscle transversely to the extent of about one-third of its width, a little below the lower third of the muscle. The incised fibres are then so far severed from the remainder of the muscle that their upper portion, when turned downward, will reach Poupart's ligament without any considerable tension. This turned flap is now fastened to the conjoined tendon at one side, and to Poupart's ligament on the other, with formalin catgut, after the cord has been placed upon it so that the cord rides, as it were, on the muscular flap. The gap caused by the resection of the flap is now covered by uniting the outer margin of the rectus muscle with the broad abdominal muscles. The aponeuroses are united above the cord by continuous suture, thus forming a very strong muscular wall, which may be of importance in the case of large and direct hernias. It is possible that the removal of the sac may thus be rendered unnecessary in the case of small hernias.—*Medical News*, September 16, 1899.

**Acute Suppurative Cholecystitis, with Isolation of the Typhoid Bacillus Eighteen Years after an Attack of Typhoid Fever.**—Hunner (*Bulletin of the Johns Hopkins Hospital*, August–September, 1899) has reported the case of a woman, fifty-four years old, who sought treatment for a large abdominal tumor. She gave a history of remittent fever at the age of thirty-six years, which kept her in bed for two weeks, after which she insisted on getting up, although her illness continued for two months. Typhoid fever existed in the neighborhood at the time. The enlargement of the abdomen had been noticed three and a half years previously, after a serious illness of six weeks' duration. This illness began suddenly as a severe pain in the right side, radiating down into the right inguinal region. The pain became intermittent in character, the attacks lasting half an hour or more, and leaving the patient nauseated and with abdominal tenderness. There were no vomiting and no jaundice, but there had been several attacks of diarrhœa. For two years subsequently the patient was well, though suffering occasionally with slight pains and soreness in the right side. She also observed a small movable mass in the right lower quadrant of the abdomen. Eighteen months before she came under observation the attacks of pain increased in frequency and severity, and often after a paroxysm the woman could not bear the weight

of her clothing. Recently she had been confined to bed for short periods and had lost weight and strength. On physical examination a large cyst was found springing from the left ovarian region. The right ovary was represented by a hard movable mass, of the size of a fist, lying high in the lower right abdominal quadrant. Operation was undertaken, both tubes and ovaries, with the ovarian cyst, being removed. Numerous adhesions to the intestines and omentum were severed or torn apart, and an adherent appendix was removed. The period of early convalescence was without special interest, the abdominal wound being found healed on the tenth day. On the fourteenth day the patient complained of nausea, and she vomited several times duringt he afternoon and evening. There were no distention and no particular tenderness. She was more comfortable on the following day, there being no nausea or vomiting. The temperature reached 100.3° F., and the epigastrium was somewhat sensitive. On the sixteenth day she suddenly began again to complain of great pain in the epigastrium. Her expression was anxious, and there was profuse perspiration. In the epigastrium peristaltic waves from the distended stomach were visible, and at the right costal margin a sensitive tumor, dull on percussion, could be palpated. On the seventeenth day her condition became very critical. A visible tumor, exquisitely tender, projected from the costal border in the right hypochondrium, and the gastric distention was even more marked than before. The leucocytes numbered 29,000. A second operation was now undertaken, and cholecystostomy was performed, with evacuation of the contents of the greatly distended gall-bladder and the establishment of permanent drainage. No stone was found at the operation, but a pea-sized calculus was discharged a week later. The patient made an uneventful recovery, constantly secreting large quantities of bile until the spontaneous closure of the fistula a month later. Cultures and glass-slide smears were taken from the peritoneal exudate outside the bladder and from both the mucoid fluid and the pus within the bladder. Both culture and smear from the peritoneum were negative with regard to micro-organisms, whereas in both the mucoid fluid and the pus bacilli were found that conformed in general with typhoid bacilli, though differing somewhat in morphological appearance.

**Cultures from the Blood in Septicæmia, Pneumonia, Meningitis, and Chronic Diseases.**—As the result of a study of the literature, in conjunction with personal experiments, White (*Journal of Experimental Medicine*, vol. iv., Nos. 3 and 4) has reached the following conclusions: (1) Blood for bacteriological examination during life should be taken directly from a vein and in considerable quantity. (2) Absorption of toxins is the most important feature in cases of septicæmia; pyogenic bacteria invade the general circulation in a rather small proportion even of severe cases, and as a rule late in the course of the disease. (3) General infection by the pneumococcus can be demonstrated occasionally in the late stages of acute lobar pneumonia. (4) The value of blood-cultures as a means of diagnosis in obscure cases of septicæmia is limited by the fact that invasion of the blood by the specific organism cannot be demonstrated during life in the majority of cases. Positive cultures are highly valuable, but negative cultures do not exclude local septic infection. (5) The detection of specific bacteria in the blood in cases of septicæmia and of pneumonia is ground for a very unfavorable prognosis in most instances. (6) General terminal infections with pyogenic cocci occasionally occur as an immediate cause of death in cases of chronic disease. Local infectious processes play this part more frequently. (7) So far as experiments have gone, invasion of the blood by bacteria during the death agony, with subsequent distribution of the germs to the organs by way of the circulation, is a rather uncommon occurrence. (8) Owing to the relative infrequency of agonal invasion, it may be concluded that in the majority of cases in which the autopsy is performed promptly after death the bacteria that are found in the organs have succeeded in reaching these organs previously to the death agony and are associated with the course of the disease. (9) The presence of bacteria in the organs when autopsies are performed late is due in many cases to post-mortem extension from one organ to another, and in some cases to the post-mortem growth of small numbers of germs that were distributed through the organs by means of the circulation.

**Molluscum Fibrosum.**—In the *Wiener klin. Wochenschrift*, August 17th, Dr. P. Merken takes the ground that molluscum fibrosum is to be regarded as a congenital deformity of progressive nature similar to nævus. It is a neoplasm of benign growth in general, but with a slight tendency to malignancy. Seventeen cases have been put on record as undoubtedly congenital in origin, and the writer finds that many others show the influence of heredity. On this fact, and also that the majority of instances develop in early life, is based the claim that these fibromata are congenital. The frequency of coexisting mental defect is also pointed out.

**Cocainization of the Spinal Cord.**—Bier (*Wiener medizinische Blätter*, August 17, 1899) cocainized the spinal cord in six patients, a healthy colleague, and himself in the following manner: With a very thin needle he performed a typical spinal puncture, and then injected into the cord small doses of cocaine (0.005—0.01—0.015), at the same time taking care that the cerebro-spinal fluid did not gain an exit. This was followed by complete loss of sensation, which even with the smallest dose (0.005) embraced two-thirds of the entire body; this loss of sensation began in from five to eight minutes at the lower extremities and gradually ascended to the sternum. In larger doses the loss of sensation spread over the entire body with the exception of the head. The anæsthesia lasted about forty-five minutes with 0.005 of cocaine. In the six patients, the following operations were performed without any pain whatsoever: (1) Resection of a tuberculous ankle-joint; (2) sequestrotomy in an old osteomyelitis of the tibia; (3) resection of an ankylosed knee-joint; (4) curettage of a tuberculous area in the sacrum; (5) osteotomy for osteomyelitis. In three instances disagreeable after-effects were entirely absent or present to but a slight degree. In the remaining three instances, as well as in the two physicians, disagreeable after-effects such as are seen in general narcosis—vomiting and headache—did occur. These were in fact more violent and lasted much longer than is generally observed in chloroform anæsthesia. These bad effects occurred after a few hours, so that they could not be attributed to the toxic effect of the cocaine, but must be due to a direct irritation of the central nervous system. This anæsthesia is very likely produced by a direct effect of the cocaine upon the non-medullated nerve fibres, perhaps upon the ganglia. The sensation of pain disappears first, whereas the sensation of touch is diminished or disappears only after a long time and with larger doses of cocaine. Sensations of warmth and cold remain intact, but the pain produced by contact with hot substances is very much diminished. On account of these disagreeable after-effects, Bier has given up this cocainization of the spinal cord; still his method may be of value in instances in which general anæsthesia is contraindicated and the Schleich method is inadequate.

**Huntington's Chorea.**—Cases of Huntington's chorea have not been very numerously reported upon from Germany, hence Lewenfeld's communication (*Centralblatt fur Nervenheilkunde und Psychiatrie*, June, 1899) is of interest, especially since there was little mental degeneration; nor was there any marked psychical change in an uncle of the patient, who was also affected by the disease. This, with other observations of the author, inclines him to oppose the use of the term "dementia choreica," as generally applied to this disease.

**Tetanoid Seizures in Epilepsy.**—Tonic or tetanoid epilepsy, L. P. Clarke (*American Journal of Insanity*, No. 55, 1899) holds, judging from literature and his experience at Craig Colony, to be a comparatively rare condition, though he is not disposed to make a special type of epilepsy of such tetanoid seizures. The history of a patient is presented, who, prior to the time of the observations, had had grand-mal seizures. In the tetanoid seizures the head was first slightly rotated to the right and then decidedly to the left. Then the spasm passed rapidly over the entire body, apparently bilaterally, from head to foot in a wavelike manner. All the muscles were in tonic rigidity each time for fifteen to twenty seconds. The back was well arched as in tetanus; the muscular rigidity being so great that the body could be raised from the floor by lifting the ankles, the occiput supporting the upper end. These tonic spasms occurred for a period of three hours, and were not intermingled with those of a clonic nature.

**Headache, Deafness, and Tinnitus Aurium.**—A novel treatment by application of hot air is suggested by Dr. E. L. Vansant (*The Philadelphia Medical Journal*, September 9th). The hot-air syringe consists of a small chamber containing either a piece of carbon or several diaphragms of metal. This is held over a flame until heated. Coming off of the chamber, anteriorly, is a nozzle with adjustable tips. The air enters the chamber from behind and is heated while passing through. The instrument is small in size and is held by a handle placed at a convenient angle. The air to be heated is obtained from the usual air-condenser. The amount of heat produced may be varied at will, from a mild warmth to a burning degree, and depends upon how hot the chamber is heated, how close the nozzle is held, etc. The nasal accessory sinuses are syringed by the stream of hot dry air thus obtained. In preparing the nasal chambers for treatment, the mucosa is first shrunken by applications of cocaine or eucaine, used alone or followed by watery solutions of the suprarenal capsule of the sheep. The hot air is directed against the openings of the sinuses, or, if necessary, a small catheter is used. When the middle ear is treated, the air is passed through a Eustachian catheter. The treatment, when properly carried out, is not painful, but is rather agreeable to the patient.

**Effect of Quinine upon the Malarial Plasmodium.**—Lo Monaco and Panichi (*Deutsche Medizinal-Zeitung*, August 14, 1899) state that if the blood containing young plasmodia is placed under the microscope and a few drops of a watery solution of sulphate of quinine (1:5,000) are added, it is observed that the parasites contract themselves by means of their pseudopodia and the contained pigment tends to accumulate in the centre. In about fifteen minutes the parasite again stretches itself, the pigment particles return to the periphery, and finally the plasmodium assumes once more its slow movement. In young but more developed forms, which occupy about two-thirds of the erythrocyte and contain much more pigment, quinine pulls together the plasmodium, and draws in the pseudopodia, so that the parasite attempts to assume a circular form; the pigment particles, which are found in large numbers at the periphery, become actively motile. Following this, all pigment particles gather in the periphery of the micro-organism, which assumes a round form. Soon after we notice that the pigment particles move about and the plasmodium emerges from the red blood cell and lies at its side. In the pre-febrile stage, the plasmodia, which practically fill the entire erythrocyte, do not emerge therefrom when in contact with quinine, but rather draw themselves together and then again stretch out, and finally assume a circular form, thus appearing much smaller. The movement of the pigment becomes very active, and it wanders from the periphery to the centre of the plasmodium. When this movement has reached its acme, some of the pigment particles leave the parasite and deposit themselves at a greater or less distance from it. From these observations it is seen that on account of the quinine the plasmodia leave the red blood cells and thus undergo degeneration. Furthermore, they sanction the clinical rule that quinine is to be given always before the attack, and never during it.

**Constipation and Diarrhœa.**—R. Schütz (*Wiener medicinische Blätter*, August 17, 1899) says that the abnormal function of the intestines may be due to three factors, namely, a pathological condition of the muscular apparatus, unusual irritation, and obstruction to the passage. The muscular apparatus may be congenitally atrophic (hypoplasia), it may become atrophic, or it may be normal but react very weakly (atony). According to Lesshaft, abnormal conditions of the abdominal muscles also influence intestinal peristalsis. Unusual irritation is caused by food stuffs, the central nervous system, the blood, or external agencies. Thus a diminution of free hydrochloric acid causes fermentation of the carbohydrates and decomposition of fats with irritation of the small intestines and diarrhœa, just as in gastric carcinoma, on account of the diminution of food ingested, constipation occurs. Constipation with increased hydrochloric acid is caused, according to Fleiner, by the bactericidal action of the hydrochloric acid, with resulting diminution of fermentation and peristalsis. This hypothesis is rendered doubtful by the fact that the stomach has a tendency rapidly to pass along fluid and semifluid substances. It is also very questionable whether the intestines contain sufficient bacteria to continue the process of decomposition. Experiments of Schütz have proven negative in this direction. Therefore he believes that constipation in such instances as gastric ulcer depends upon the fear of the patients of pain and the selection of their food stuffs. Under this heading comes the constipation due to increased excretion of water. For diagnostic purposes examination of the stools is necessary. An admixture of mucus, provided it does not look like a coat of varnish, always speaks for catarrh except when a laxative has been administered. A differentiation is also to be made between mucous colic and membranous enteritis, the former occurring periodically and being of nervous origin, the latter usually being a catarrh. Nothnagel prefers to call the former mucous colic, the latter chronic colitis. Otherwise, mucus always speaks for catarrh (in a constipated stool). In diarrhœal conditions microscopic examinations must often be made in order to determine whether the condition is of a dyspeptic or nervous origin. Pure mucus without fæces, or very little of it, indicates catarrh of the lower bowel; mucus with fæces, catarrh of the small intestines or upper part of the large. Particles of muscle and mucus point to catarrh of the small gut. In chronic colitis the stools often have a sandy consistency. Small masses, frequently evacuated, point to inflammatory process of the lower bowel, but are frequently a nervous symptom. In a normal stool undigested vegetable particles are often found.

MEDICAL RECORD:

## A STUDY OF ANGER.

THE manifestation of the feeling of anger is one of great importance for moral and physical education, but there has hitherto been upon it little literature worth reading. A paragraph in a text-book, linking it with the emotions of love and fear and hate, is generally all the notice it receives. In medical works it is regarded as a symptom of epilepsy and insanity, and a possible cause of other diseases, while novelists describe the passion of anger with a fine liberality of imagination, ranging all the way from the horrors and tortures of savagery and warfare to the climax of hatred and revenge in the murder of a Nancy or a Tito.

But anger as a daily universal experience, with a distinct physical reaction, has not been so widely studied. The child who screams and bites his nurse when carried off to bed, the schoolboy who fights another who sticks out his tongue at him, and the business man who damns an employee for stupidity, are all material for study, as well as the extreme cases that lead to crime or are the manifestations of paranoiac suspicion and rage.

That all anger is primarily a physical and secondarily a moral manifestation, is well shown by the very suggestive bit of work published by G. Stanley Hall, in the *Psychological Review*, vol. 9, 1899. In "A Study of Anger," Mr. Hall has departed from the material of literary and world-famous pages, of which, however, he gives a very interesting review, and depends on original material which he has been collecting from reliable observers for several years.

The human tendency to rage seems greater the nearer man is to the savage and animal type, and the more he is obliged to struggle for his food. "Primitive man had no regularity of meals, working-hours, or occupations, but days and weeks of idleness, alternated with, and prepared for, by periods of excessive strain in hunting and migration and warfare. Into such life rhythms, criminals and degenerates tend to lapse." On the other hand, the term "gentleman" is held by some to imply a command over one's passion of anger above all others.

In Mr. Hall's collection of experiences, coming from some two thousand cases, we find confessions of very trivial causes of irritation and vexation. Some people have personal antipathies to certain physical characteristics in others, freckles, red hair, bad teeth, a peculiar laugh; while others feel decided aversion to personal habits, such as smoking, or eating in a slovenly way. Others are made furiously angry by being thwarted or denied their freedom, others by being slighted or gossiped about or contradicted. Jealousy, injustice, overwork, teasing, ridicule, mocking provoke others to rage.

In all cases there were physical sensations accompanying the mental sense of anger, but these differed greatly with the individual. Eighty-seven per cent. describe flushing, and twenty-seven per cent. describe pallor as characteristic of anger. The heart bounds or beats rapidly, and several cases of death due to cardiac lesion are ascribed to anger. Some people have peculiar feelings in the throat and mouth, others become dizzy or faint; thirty-five per cent. of the cases report tears, and in twenty cases attacks called bilious are ascribed to anger. Salivation is generally more copious; the frequent swallowing of it probably causes the nausea which some mention as a concomitant of their anger; and blowing it in bubbles with a panting breath is undoubtedly the "frothing at the mouth" that is sometimes described. We agree with Mr. Hall that "it is a long cry to associate the salivation of anger with primitive anticipation of savory food," but when it comes to ascribing the abhorrence of spitting which is common in children and primitive people to a long experience of contagion of morbific germs through saliva, and saying that we have here "an instinctive prophylaxis against contagion," we feel that the conclusion is a little far-fetched.

The sounds indicative of anger are interesting, as passing from the monotonous cry of infancy, through the animal-like noises of childhood, to the threats and oaths of adult life. In many cases, paralysis of the throat is reported, and inability to speak above a whisper, or without crying or trembling, but in the greater number making a noise seems to be a natural expression of anger. The very close connection between intense muscular tension and loud phonation is shown in the characteristic cry of epilepsy, which resembles the battle-cry of various savage tribes, while college yells at athletic contests are, according to Mr. Hall, "toned-down cries of defiance."

The tendency to bump and butt with the head, so noticeable in childish fits of temper, he thinks, may be related to a previous phyletic experience, when early vertebrates, both aquatic and terrestrial, accumulated an ancestral experience of moving head first, breaking their way through water and obstacles.

Biting and scratching as a relic of animal hatred is common in childhood, and a strong jaw is considered a sign of force, compared to the weak, passionless character of a person with a weak jaw.

In general, temper decreases in the violence and frequency of its outbursts as the child approaches adolescence, but, if uncontrolled, develops into great irascibility with old age. The expansion of the mind and the reason, the work of the day, conscience and religion seem to tone down the violence with which the body seeks to relieve itself of its tension by giving vent to anger.

The study of reaction, and whether or not it is accompanied by humiliation, penitence, and atonement, is an interesting topic which the physical and moral healer could work out to advantage. The training of youth to self-control has hitherto been left to the individual mother and teacher, for discussion on the ethics of the upbringing of children generally degenerates into a sentimental dissertation on the rod. According to the temperament and environment of the child different means may be used to help him to self-control: a mirror to reflect facial contortions, a joke, the repetition of a text or prayer serve some by breaking for a moment the tension, while in over-indulged children Dr. Hall advocates "a vigorous application of Dr. Spankster's tonic," as working wondrous and sudden cures. Isolation from social intercourse helps; plain, unvarnished rebuke, the natural consequences of a tearing, smashing temper, and seeing the disagreeable effect of other ill-tempered children, are means often heplful to self-control, while some boys can work out their salvation only by a certain amount of fighting.

The state called irritability is due to loss of inhibition. Fatigue and loss of sleep are often responsible for it, and the irritability of convalescence is a sign that the lower reflexes are restored before the higher. Some forms of insanity consist essentially in the loss of this higher power of self-restraint; and not only anger but mania, acute and chronic melancholy, and suicide are thus explained. Good health, plenty of sleep, and removal of irritating causes, with occupation and amusement, seem to sum up the natural methods of cultivating self-control, without which crime and suffering are engendered.

---

## SOME FURTHER REMARKS ON CHRISTIAN SCIENCE.

In the August number of the *North American Review* Mr. W. A. Purrington continues his consideration of the case against Christian Science. Taking as his text the proposition that "Publicity will destroy the cult far more quickly than legislation," he proceeds to lay bare the absurdities inherent in Mrs. Eddy's teaching by quotations from her writings. The fact that after a curriculum of only three weeks and on the payment of a fee of $300 the title of doctor of science was granted at Mrs. Eddy's college to those desirous of receiving that degree and willing to part with the money for that purpose should, if nothing else will, open the eyes of the public both to the ridiculous and the nefarious aspects of the question. Undoubtedly, however, the point that especially appeals to the masses in regard to Christian Science is the ingenious mingling of religion with the mundane art of healing. Unfortunately religion is and always will be made the cloak for humbug of every description. The conclusions arrived at by Mr. Purrington are as follows:

First: As a mere religious or philosophic theory Christian Science never would have had any vogue. Its fascination lies in its pretended cures. No one suggests taking action to restrain it as a form of worship. The most that has been suggested in regard to it has been that its ignorant votaries should not be allowed to trifle with the life and health of adults, children, and the entire community by assuming the treatment of all classes of disease, including surgical cases and contagious and infectious maladies. To say that it is an infringement of religious liberty to require the same skill and knowledge of Christian Scientists engaging in the business of curing the sick for hire as is required of Presbyterians or Catholics in the same business, shows ignorance of the constitutional doctrine of the Mormon cases, or carelessness of statement, or such wilful misstatement as Mrs. Eddy personally was guilty of when she said infringement of copyright is theft, punishable criminally.

Second: Christian Science has no healing power peculiar to itself, as distinguished from faith cure or any other method of diverting the mind from the ills of the body. If it had such divine power, its application would be universal; it would be effective in surgery as in physic. . . .

Third: Why is it then that Christian Science is credited with these marvellous cures, if its foremost professors cannot bring forward any better proofs of them than are afforded by certificates no better in manner and degree than those accompanying every quack nostrum that is advertised? The explanation is simple. In perhaps the majority of cases to which physicians are called nothing more is needed than regimen and the mental stimulus that comes to the patient with the knowledge that he is under skilled care. If a physician falls ill, he calls another to attend him chiefly for the sake of this mental stimulus and to eliminate the personal factor. . . . In all self-limited or feigned cases whatever removes the mental tension may be beneficial. Many patients would get well without any attendance at all. To take an illustration: Childbirth, in which Christian Scientists profess great success, is not a disease, but the operation of a normal function. In the absence of complications, attendance is not necessary, although it may be desirable. But in the presence of certain complications the very highest skill is necessary to save life. Will any sane person say that because in the vast majority of cases children may be brought into the world safely under the attendance of a Christian Scientist, such a person is to be pardoned who undertakes such a complication as that of placenta prævia with neither medical skill nor knowledge? Will any parent be willing, in case a child's artery is severed, to call a Christian Scientist rather than a surgeon? Upon the answers to these questions depends the acceptance by reasoning persons of Mrs. Eddy's theory and claim that her followers can cure all forms of human maladies and injuries, and that they should be allowed to treat medical and surgical cases without the responsibility for malpractice that rests upon "medical men." *The Outlook* has these pertinent remarks in regard to the danger of calling in Christian Science aid to the sick: "Suppose a Mormon were to set up as a pilot, claim divine guidance, and insist on his right to take steamships in and out of New York harbor on the strength of his proficiency in the Book of Mormon, would it be a violation of the liberty of the individual to prohibit

and put him in jail if he persisted? Yet the danger to the community from incompetent pilotage of an ocean steamer would not be so great as the peril from incompetent treatment of certain contagious diseases." When those members of the public who are apt to believe in the efficacy of Christian Science treatment can be made thoroughly to understand that a course of three weeks' training is not sufficiently long to render a person, even with spiritual aid, qualified to treat injuries and diseases, and that by employing such practitioners in many instances not only are they endangering their own lives, but also those of their neighbors, perhaps they will pause and ponder.

In the mean time strong measures should be taken to prevent parents and guardians from employing unskilled advice for their children or wards.

## THE FALL MANURING OF CENTRAL PARK.

The season has arrived for the annual spreading of manure over the greenswards of Central Park. At least, that which they spread, just as the carriage population begins to return to the city each year, the gentlemen of the park department are pleased to designate as manure. What it is and where they get it, and how they treat it to give it so horrible an odor, they alone know. A little of that consideration for the olfactories which the lady showed when she poured cologne into the sample of morning urine the doctor had ordered sent to his office, would be appreciated by thousands of lovers of the beauties of nature.

If the eye must be offended by this black mantle shutting out the green until the snows fall in their pity and hide with a pure covering of white this uninviting prospect, let the nose, at least, be spared. The manure should be scented, or, at least, disinfected. If interviewed in this connection the park gentlemen will tell you that the odor of manure is healthy. Be this as it may—we are prepared to accede the point and grant to those who seek health by inhalations of this nature the privilege of continuing. We reserve, however, for those others who do not feel the need of the manure treatment the right to resist an enforced application of it. When the older scientists put forth the proposition that the ammoniacal odors arising from the dung-hill were salubrious, they had in mind the real old-fashioned country article. If they could come back to earth one of these glorious autumn afternoons, and smell the fraudulent, adulterated article which the department is attempting to foist upon a gullible public as "just as good as the original," they would be glad to go back again—no matter whence they came.

**Transactions of the Moscow Congress.**—It is announced that the first four volumes of the Proceedings of the Twelfth International Medical Congress, held in Moscow, will be ready for publication in the course of the present month. The remaining three volumes will, it is said, be ready by the end of the year.

## News of the Week.

**The Hospital Ship "Solace"** arrived in San Francisco from Manila on October 7th.

**Dr. William H. Howell,** professor of physiology, has been made dean of the Johns Hopkins Hospital in place of Dr. Osler, resigned.

**Smallpox in an Orphan Asylum.**—There has been an epidemic of smallpox at the Orphans' Home in Dayton, Ohio, thirty-three cases having occurred there up to October 5th.

**The British Red Cross.**—The president of the British Red Cross Society, Lord Wantage, has issued an appeal for contributions to aid in the work of the society, which, he says, will provide two hospital railway trains and a hospital ship.

**Inspection of Emigrants.**—Health Officer Doty of this port has gone to Europe to visit the principal Continental ports, where he will consult with the authorities and steamship agents in relation to the detention at the port of embarkation of certain emigrants previous to their leaving for this country. This detention is to cover the incubation period of the ordinary infectious diseases, especially smallpox.

**The Yellow-Fever Situation** at Key West remains practically unchanged, the number of new cases reported being from twenty to twenty-five a day. This number is less than it was two weeks ago, however, and it is believed that the worst of the epidemic is now over. In New Orleans there are but few cases, and those generally of a mild nature. In Havana only three new cases were reported during the first ten days of October, and the sanitary authorities believe that hereafter there will be only a few sporadic cases, the danger of an epidemic being practically past.

**The Health of American Troops in Cuba.**—Dr. Havard, chief surgeon of the department of Santiago and Puerto Principe, has recently made a trip through the two provinces with General Wood. He reports the health of the men at the various posts to be surprisingly good, the percentage of sick seldom being more than five, the diseases being chiefly malarial. He says that the question of taking care of American troops in a tropical climate will always be a serious one and difficult of solution. He thinks the number of troops from this country should be reduced to the minimum, native regiments, partly officered by Americans, being organized to take their place in the army of occupation.

**Milk Dealers Punished.**—The inspectors of the New York board of health recently caused the arrest of a number of dealers on the east side for selling adulterated milk. On trial three were found guilty and were fined amounts varying from $15 to $100.

**The Plague in Russia** is reported to be of the pneumonic type, and great fears are entertained that it will spread from the southern provinces all over the empire

and thence make its way to western Europe. The insanitary condition of the huts of the Russian peasantry, especially in winter, is such as to make the suppression of a disease such as the plague a most difficult, if not impossible, task.

**The Study of Tropical Diseases.**—The Liverpool School of Tropical Diseases sent an invitation to the United States government to attach an official delegate to the malarial commission of the school now working in West Africa. The invitation was, however, received too late to permit of a medical officer being detailed by the government to accompany the expedition.

**Congress of Italian Alienists.**—The tenth congress of Italian alienists was held in Naples from the 10th to the 14th of October, under the presidency of Professor Tamburini. The following were the subjects discussed: (1) Practical methods of individual psychological investigation in asylums and clinics; (2) the light which has been, and may be, thrown by anatomical data on normal and pathological psychology; (3) psychiatry and the study of the individual and his activity in social relations; and (4) intoxications and infections in the pathogenesis of mental diseases and neuropathies.

**A Discussion on Typhoid Fever.**—At the meeting of the New York State Medical Association, to be held in this city October 24th–26th, the following papers are promised for the discussion on typhoid fever: "The Advance in Our Knowledge of Typhoid Fever," by Dr. Herman N. Biggs, of New York; "The Bacteriology of Typhoid Fever," by Dr. W. H. Park, of New York; "The Clinical Diagnosis of Typhoid Fever," by Dr. William Osler, of Baltimore; "Statistics of Typhoid Fever at the Roosevelt Hospital for Ten Years," by Dr. W. H. Thomson, of New York; "Typhoid Fever in the Massachusetts General Hospital during the Past Fifty Years," by Dr. Reginald Fitz, of Boston; "Some Phases of Typhoid Fever as seen in Bellevue Hospital," by Dr. A. A. Smith, of New York; a paper (title not given) by Dr. E. G. Janeway, of New York; "Typhoid Fever in Children," by Dr. Abraham Jacobi, of New York; "The Local (non-surgical) Treatment of the Intestinal Tract in Typhoid Fever," by Dr. De Lancy Rochester, of Buffalo; "The Treatment of Perforation of the Bowel in Typhoid Fever," by Dr. W. W. Keen, of Philadelphia; and "Eye Complications in Typhoid Fever," by Dr. A. Hubbell, of Buffalo.

**Dr. John G. Clarke,** associate in gynæcology in the Johns Hopkins Medical School, has been elected professor of the same subject in the University of Pennsylvania, to succeed Dr. Penrose.

**Tuberculosis Cures.**—Italy is prolific of "cures" for tuberculosis, the latest being announced by Dr. Ruata, of Perugia. This consists in the inhalation of a mixture of alcohol, creosote, and chloroform in suitable proportions.

**Dr. J. G. Wishard Honored.**—The shah of Persia has conferred upon Dr. J. G. Wishard, medical director of the American Presbyterian Hospital in Teheran, the decoration of the Lion and the Sun. The shah has repeatedly shown his good will toward the work of the American medical missionaries in Persia.

**The Mississippi Valley Medical Association.**—The meeting of this society last week in Chicago, a report of which will be found in another column, was a very successful one. There were about six hundred members in attendance, and one hundred and sixty-four new members were elected. The next meeting will be held in Nashville, Tenn.

**The Johns Hopkins Medical School** has opened with thirty-five women in the school, six of whom are freshmen, with fourteen in the graduating class. In the first class that graduated there was one woman. Seven women in all have taken their degree from this school, and nearly every one now holds the position of resident physician in some well-known hospital in some part of the country.

**College of Physicians of Philadelphia.**—At a stated meeting, held October 4th, Dr. David L. Edsall read a paper entitled "The Relations of Water to Metabolism," in which he pointed out that excessive ingestion of water caused increased elimination (and diminished retention) of nitrogen, but that no appreciable effect is induced upon absorptive activity. Dr. W. Joseph Hearn read a report of "A Case of Arterio-Venous Aneurism in Scarpa's Triangle." The patient was a young colored man, without a history of syphilis, the lesion being attributed to pressure upon the vessels by the use of a spade in digging. The condition was thought to be an aneurism and the external iliac artery was ligated, but as the sac failed to diminish in size it was incised, when furious hemorrhage occurred. Ligation of the femoral artery and vein above and below the aneurismal dilatation, and of an additional large vessel, was eventually required. The patient recovered without complication, in the course of a few weeks. At a stated meeting of the Section on General Medicine, held October 7th, Dr. A. A. Eshner exhibited a case of probable syphilitic osteitis in a colored man who presented a painful swelling of the right humerus and in slighter degree likewise of the left and some pain also in the legs. The patient had been rachitic in childhood, and in diagnosis ossifying myositis, deforming ostitis, and osteosarcoma were excluded. Improvement ensued upon specific treatment, although a syphilitic history was not clear. Dr. S. McC. Hamill exhibited "An Interesting Heart Case," in a man presenting a loud, high-pitched, musical systolic murmur heard all over the chest, though best in the mitral area, and a less marked diastolic murmur, heard best in the course of the sternum. Dr. A. Stengel reported a case of hysterical dyspnœa occurring in a colored girl, whose respiratory frequency ran up to fifty per minute, without corresponding acceleration of pulse or elevation of temperature. There was, besides, some hæmoptysis, but without physical evidence of visceral disease. The condition ensued upon fright and ceased upon suggestive treatment. Drs. J. H. Musser and J. D. Steele

presented a communication entitled "Some Cases of Dilatation of the Stomach," reporting five cases in male students between the ages of twenty and thirty years in which the diagnosis was made by physical methods, including distention with water and air, lavage, percussion, palpation, and auscultation, and a study of the gastric chemistry.

**Quarantine against Tuberculosis Not to be Established.**—The State board of health has decided not to quarantine California against the consumptives of other States. It has adopted a resolution, however, recommending that in all State institutions those inmates afflicted with tuberculosis be kept apart from the others.

**A Busy Doctor.**—There is much sickness prevailing among the Doukhobors in the Northwest at the present time. Their medical adviser, Dr. Vera Welistchkina, is described as a tiny, slender, dark-eyed woman, who, after having taken her degree of M.D. in Switzerland, followed these people to their adopted homes. Besides being a physician, she acts as nurse and interpreter and guide to many hundred souls. At present writing she must more than have her hands full.—*Journal of the American Medical Association.*

**Navy Department,** Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending September 30, 1899. September 25th.—Passed Assistant Surgeon C. E. Riggs detached from the *New York* and ordered home to wait orders. Passed Assistant Surgeon E. S. Bogert ordered to the *New York* October 3d. September 26th.—Passed Assistant Surgeon C. P. Kindleberger detached from the Philadelphia naval hospital and ordered to the *Iowa*. Passed Assistant Surgeon M. S. Guest detached from the *Wabash* and ordered to the Philadelphia naval hospital. Passed Assistant Surgeon R. P. Crandall detached from the *Iowa* and upon relief to proceed home and wait orders. September 27th.—Assistant Surgeon B. L. Wright ordered to additional duty on board the *Monterey*. September 28th.—Surgeon T. A. Berryhill detached from the *Panther* when out of commission and ordered to the *Monongahela*.

**Reciprocity in Medical Licensing.**—It is an anomalous condition that exists at present in the United States in respect of the laws regulating medical practice. A physician of no matter how many years' practice, upon changing his residence to another State must in most cases go before a board of examiners and satisfy them as to his attainments before he can earn a living in the practice of his profession. Many have advocated the recognition by the authorities of one State of a license granted by another State, but, of course, a necessary preliminary to this reciprocity in licensing is the establishment of uniform requirements for the license to practise throughout the United States. The Wayne County (Mich.) Medical Society has taken steps looking to this very desirable result, and has sent out a circular to the authorities in the different States and Territories asking their views in the matter. The replies thus far received have been in the main satisfactory, and the committee having the matter in charge is encouraged to continue its labors. They are also endeavoring to obtain the co-operation of other medical societies and of individuals in the furtherance of the work. Information as to the work already accomplished may be obtained of the secretary of the committee, Dr. E. Amberg, 32 West Adams Street, Detroit, Mich.

**Dr. Jules Simon,** of Paris, physician to the Hôpital des Enfants Malades, died recently from heart disease following influenza.

**Dr. Fernando Gonzalez del Valle,** the oldest physician in Cuba, died in Havana on August 14th, at the age of ninety-eight years. He was graduated in medicine in 1823, and had practised from that date up to within a short time of his death in that city. He held for many years the chairs of pathology and of clinical surgery at the University of Havana.

**Death of a Physician from Strychnine Poisoning.**—A medical practitioner in London gave a patient a bottle of tonic medicine which the patient complained made her ill. In order to assure her that it was not poisonous, the doctor took several swallows of it. When he arrived home he had a convulsion and died not long afterward. Analysis showed that the bottle contained a large amount of strychnine, the doctor in compounding the medicine having used a solution of strychnine by mistake for chloroform water.

**Obituary Notes.**—Dr. Joseph H. Smith died at Plattsburg, N. Y., on September 30th, at the age of seventy-eight years. He was a graduate of the Albany Medical College in the class of 1846. He was once physician at Sing Sing prison, and later at Dannemora.—Dr. Frederick Olin White, of New Haven, died on October 5th of apoplexy. He was born forty-seven years ago in Seymour, Conn., and was graduated from the Yale Medical School in the class of 1877.—Dr. Pedro Jiménez died suddenly in this city on September 30th. He was a resident of Porto Rico, but came to New York some years ago to study medicine, and after his graduation served a term on the house staff of the Columbus Hospital. He was about to return to Porto Rico to begin practice.—Dr. Henry J. Lee, of Lydia, S. C., was shot by his son, also a physician, and died on October 5th. Dr. Lee was a graduate of the Medical College of the State of South Carolina in the class of 1854.—Dr. Edward E. Lloyd was found dead on October 3d, on the steps leading to his office at Tamaqua, Pa. He was for eight years a surgeon in the United States army. Two sons are physicians in practice at Scranton.—Dr. John H. Brownlow, of Ogdensburg, N. Y., died suddenly on October 10th, in an attack of angina pectoris. He had just finished reading a paper at the annual meeting of the Medical Association of Northern New York. He was sixty-five years old, and was a graduate of the Medical Department of the University of Georgetown, Washington, in the class of 1865. A widow and two sons survive him.

# Reviews and Notices.

PYORRHŒA ALVEOLARIS AND ITS RELATIONS TO GENERAL MEDICINE. By JOHN FITZGERALD, L.D.S., R.C.S.I. Pages 57. London: The Medical Publishing Company, Limited.

THE condition known also under the name of interstitial gingivitis is here briefly described. Some of the writer's statements are rather sweeping and unsupported by sufficient scientific data to make them fully trustworthy. The work is intended, however, as an outline of present knowledge and methods of treatment, and as such has been well constructed.

GENERAL PATHOLOGY, or the Science of the Cause, Nature, and Course of the Pathological Disturbances which occur in the Living Subject. By DR. ERNST ZIEGLER, Professor of Pathological Anatomy and of General Pathology at the University of Freiburg in Breisgau. Translated from the ninth revised German edition by Drs. Theo. Dunham, E. M. Foote, Philip H. Hiss, Jr., Walter B. James, William G. Le Boutillier, and Matthias Nicoll, Jr., of New York; Dr. B. Mead Bolton, of Philadelphia, Pa.; and Drs. Leonard Woolsey Bacon, Jr., John S. Ely, and R. A. McDonnell, of New Haven, Conn. Editor, DR. ALBERT H. BUCK, of New York. New York: William Wood and Company. 1899.

THIS new edition of Ziegler's Pathology consists of a volume of six hundred and twenty-one pages, profusely illustrated by five hundred and forty-four wood engravings in black and colors, and one lithographic plate, the latter representing various cultures of pathogenic bacteria on agar-agar, gelatin, blood-serum, and potato.

There is little to say of this ninth edition that has not already been said of the eighth. Ziegler's Pathology is acknowledged by all to be *the* authority of the end of the nineteenth century, and no words of praise or of criticism from a reviewer could shake this supremacy. This is not a simple reprint of the eighth edition but an actual revision, the number of illustrations being materially increased and many portions of the work rewritten. The most radical changes are in the chapters on degenerations and on tumors. The author's views on inflammation are well known, and, while not yet universally accepted, are gaining more and more adherents. These are stated here even more explicitly than before, and in a way that ought to force conviction upon any unbiassed student.

ON THE RELATION OF THE NERVOUS SYSTEM TO DISEASE AND DISORDER IN THE VISCERA. Being the Morison Lectures delivered before the Royal College of Physicians in Edinburgh in 1897 and 1898. By ALEXANDER MORISON, M.D. (Edin.). Fellow of the College; Member of the Royal College of Physicians in London; Physician in Charge of Out-Patients to the Great Northern Central Hospital and the Children's Hospital, Paddington Green; Physician to the Saint Marylebone General Dispensary. Edinburgh and London: Young J. Pentland. 1899.

IT may be accepted as an axiom that all bodily structure and function are under the domination of the nervous system, directly or indirectly, and it cannot, therefore, occasion wonder that deranged innervation should induce alteration in function and also in structure, and, conversely, that disease of structure and disorder of function should give rise to manifestations of nervous perturbation. The subject is a most extensive as well as a most attractive one, and its study can be pursued with much profit and practical advantage. Dr. Morison has devoted himself with fidelity and industry to his assigned task, and he has provided us with a bounteous repast of mental pabulum deserving of thorough digestion and careful assimilation.

In these admirable lectures, commendable alike for their scientific character and their practical value, the following order of discussion is pursued: the anatomy, the physiology, and the pathology of visceral innervation, disorders of visceral sensibility and motility, and body and mind; and in an appendix the subject of innervation of intracranial blood-vessels is discussed. It is quite impossible within the limits of a review even to mention the many topics discussed, and we can only commend the volume for careful study at the hands of those at all interested in the matters with which it deals. The book is well printed on heavy paper, is generously illustrated and substantially bound.

TRANSACTIONS OF THE AMERICAN MICROSCOPICAL SOCIETY. Edited by the Secretary. Twenty-first Annual Meeting, held at Syracuse, N. Y., August 30, 31, and September 1, 1898. Vol. xx. Lincoln, Neb. Issued May, 1899.

THIS well-prepared report of three hundred and seventy pages reflects decided credit upon the members and their editor. The papers are as a rule of high scientific merit, and as such contribute to the advances being made in this field.

THE GROSS AND MINUTE ANATOMY OF THE CENTRAL NERVOUS SYSTEM. By H. C. GORDINIER, A.M., M.D., Professor of Physiology and of the Anatomy of the Nervous System in the Albany Medical College; Member of the American Neurological Association. Philadelphia: P. Blakiston's Son & Co. 1899.

THIS is an excellent book on a fascinating subject, and the author deserves the thanks of the English-speaking medical world for his labor in getting it up. There are works enough on general anatomy, and dry enough they are, as we all remember only too well; but the anatomy of the nervous system alone is another matter entirely, for it is one of the most interesting of all subjects of medical study at the same time that it is one of the most difficult. For both of these reasons the subject is deserving of a treatise by itself, and should not be briefly discussed in a few pages of a general work on anatomy or in an introductory chapter of a treatise on diseases of the nervous system. The opening chapter is concerned with the minute anatomy of the nervous system, our ideas of which have been so changed by the comparatively recent labors of Cajal and Golgi. Then follow chapters on the cord, the medulla, the cerebellum, and the different parts of the cerebrum. The vessels of the brain are described in a special chapter, as are also the meninges—two important subjects which usually receive such inadequate consideration in ordinary text-books of anatomy. Some fifty pages are devoted to cerebral localization, and as many more to the embryology of the central nervous system. The closing chapter is on the technique of the macro- and microscopical examination of the brain and cord. The illustrations, which number two hundred and seventy-one, are remarkably good, many being in colors and others reproductions of microphotographs. Some of the pictures are taken from other works on anatomy, but very many of them are new. The index is satisfactory.

A TEXT-BOOK OF PHARMACOLOGY AND THERAPEUTICS, or the Action of Drugs in Health and Disease. For the use of Students and Practitioners of Medicine. By ARTHUR R. CUSHNY, M.A., M.D. Aberd., Professor of Materia Medica and Therapeutics in the University of Michigan Medical Department, Ann Arbor; formerly Thompson Fellow in the University of Aberdeen and Assistant in the Pharmacological Institute of the University of Strassburg. Philadelphia and New York: Lea Brothers & Co. 1899.

THE author of a new book on the action of drugs in health and disease must have more than the usual excuse of a "long-felt want" to justify him in publishing his work, for the want, as regards the profession at large, has been long since met. However, a teacher of materia medica, if he is at all original in his methods, cannot be entirely satisfied to put any existing text-book in his pupils' hands, for none can treat of the subject in just the way the lecturer handles it, and so he writes his book for the use of his students. But the work has been so well done that the study of it will not be confined to Professor Cushny's students, and its excellence will place it at once in the front rank of treatises on pharmacology. The physiological action of the various drugs is first studied, and then their therapeutic uses are indicated. Each chapter contains a very full bibliography. The utility of the work to the busy practitioner would have been greatly enhanced by the addition of a therapeutic index.

# Society Reports.

## NEW YORK ACADEMY OF MEDICINE.

*Stated Meeting, October 5, 1899.*

WILLIAM H. THOMSON, M.D., PRESIDENT.

**Certain Aspects of Bone and Joint Diseases of Interest to the General Practitioner.**—DR. VIRGIL P. GIBNEY presented a paper with this title. Speaking of anterior poliomyelitis, and the occasional outbreaks of this disease in certain localities, he said that there seemed to be good reason for believing that this disease was infectious in its nature. Much could be accomplished by early and appropriate treatment, particularly by securing rest and protection for the limbs, and forestalling the subluxations and other deformities which prove so rebellious to later treatment. He did not agree with those who recommended stimulation and exercise of the affected parts. Some of the most distressing spinal curvatures encountered by the orthopedic surgeon had had their origin in an empyema. As a rule there was no tenderness when the bodies of the vertebræ were diseased, although exceptions to this rule were met with, particularly among adults. It was most important in examining the vertebral column for disease to determine whether or not the normal flexibility of the column was present. The age of the patient often afforded a useful clew to the differential diagnosis between malignant and tuberculous disease of the spinal column. The absence of deformity, diminished flexibility of the column, and the effort made by the patient in every movement to prevent concussion of the spine were the chief diagnostic features of interest to the general practitioner. Some years ago he had described "the typhoid spine," a condition occasionally observed during convalescence from typhoid fever. It might lead to errors in diagnosis, but it should be remembered that in these singular cases there was exquisite tenderness without deformity. The history and the rapidity of improvement would usually serve to distinguish these cases from tuberculous spinal disease. It was unfortunate that the general practitioner so seldom made a diagnosis of Pott's disease until the kyphos had already appeared. One common error was to diagnosticate as Pott's disease cases of rachitic deformity. A type of lateral curvature of the spine was not uncommonly met with in cases of Pott's disease occurring in young children, but this should be sharply differentiated from the true rotary lateral curvature, a disease met with, for the most part, in adolescence and adult life. In tuberculous disease of the hip or knee reflex spasm was almost pathognomonic, and the occurrence of lameness at certain times, with exacerbations of increasing severity, was also quite characteristic. The existence of reflex spasm was best detected by carefully moving both the sound and the affected limb in all directions through the full arcs of motion, and comparing the behavior of the two limbs during this examination.

DR. A. JACOBI pointed out that there was almost a sensation of semi-fluctuation present in sarcoma. Referring to infantile scurvy he said that it was sometimes confounded with acute rheumatism and with anterior poliomyelitis. As regards the latter, it should not be difficult to ascertain whether the failure to move the limbs was due to pain or to paralysis. As a rule, the painful subperiosteal hemorrhages observed in scurvy were not in the joints, but situated in the shafts of the long bones. The deformities following rachitis were numerous and important. Few of the important internal organs escaped its pernicious influence. Thus, the aorta might be bent upon itself, and the circulation impeded by reason of the rachitic narrowing of the thorax. The spleen and liver were generally enlarged in rachitic children, and the kidneys were sometimes displaced. It was evident, therefore, that the treatment should be begun as early as the disease was recognized.

DR. JOSEPH D. BRYANT recalled instances in which apparently insignificant injuries had been followed by necrosis of bone, or by sarcomatous change. The rheumatism which sometimes followed injuries to bones and joints he was inclined to regard as rather the result of the attendant long confinement. Attention was called to a class of cases in which necrosis of the lower and posterior aspect of the shaft of the femur was apt to be diagnosticated as rheumatism. If diagnoses were made earlier in diseases of the kind under discussion, involvement of joints and deformities would often be prevented.

DR. CHARLES N. DOWD said that the laity quite commonly believed that traumatism was a very potent factor in the production of disease of the ankle and knee. Most cases of joint disease began with inflammation in the epiphysis, and at this stage a characteristic tenderness could be elicited.

DR. JOHN B. WALKER spoke of cases of detachment of the semilunar cartilages of the knee joint, and the harm resulting from the all-too-common practice of allowing these cases to go on without treatment until an arthritis had been set up. If the diagnosis were made early, and the parts put at rest and maintained in their normal position, a cure could be readily effected. The lateral motion must be restricted, but it was not necessary to interfere with the to-and-fro movements of the joint.

DR. S. A. KNOPF spoke of the great prevalence of chronic tuberculous disorders in children, and instanced the fact that a recent examination by Neumann in the public schools of Berlin had shown that out of one hundred and twenty-five boys and one hundred and thirty-two girls who were unable to attend school regularly, one hundred and fourteen boys and one hundred and fifteen girls had some form of tuberculous disease. He asked if Dr. Gibney had had much experience with Bier's treatment of joint tuberculosis by means of the elastic bandage so applied as to produce local venous hyperæmia. The method, he said, had proved very successful in the hands of some surgeons, and so different had been the behavior of tuberculous and other forms of joint disease that some even claimed for the method a diagnostic value. In conclusion, he alluded to the great value of seaside sanatoria in the treatment of tuberculous children, and stated that in these sanatoria in Belgium and France it had been claimed that seventy to eighty per cent. of cures had been secured, while in Germany there had been fifty per cent. and in Italy thirty-five per cent. of cures reported.

DR. ANREW H. SMITH said regarding bone lesions following typhoid fever that he had seen in hospital practice a case in which a subperiosteal abscess had developed on each tibial crest, and had been followed by superficial exfoliation of bone. He also reported a case bearing on the development of sarcoma after comparatively slight traumatisms.

DR. A. ERNEST GALLANT remarked that the pseudo-fluctuation, which one of the speakers had insisted was so characteristic of sarcoma, was present in several other conditions. He expressed the belief that some cases of joint disease occurred after sprains because physicians still persisted in treating sprains by the old plan of first immobilizing the part and subsequently subjecting it to massage, instead of following the more modern treatment, viz., immediate massage. This latter method, he said, had been used very extensively by

the late Dr. Van Arsdale and by himself, and they had found that the time of treatment could thus be very greatly reduced.

Dr. Edward H. M. Sell said that he had seen one case in which, during convalescence from typhoid fever, a femoral abscess had developed, and he had been told that a cousin of this lady had had a large number of abscesses under the same circumstances.

Dr. Gibney, in closing the discussion, said that he believed that the traumatisms often thought to be the cause were, in reality, the result of bone and joint disease. In the incipient stages of such disease, and before it had been recognized, these children were prone to fall, as he believed, because of the local lesion. The Bier treatment had never appealed to him very strongly, and hence he had not given it a very extended trial. There could be no doubt about the great value of seaside sanatoria, or hospitals anywhere in the rural districts, for the treatment of tuberculous children.

## MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

*Proceedings of the Twenty-Fifth Annual Meeting, Held in Chicago, October 3, 4, 5, and 6, 1899.*

### GENERAL SESSION.

The association met in Handel Hall, and was called to order at 10:45 A.M. by Dr. Harold N. Moyer, of Chicago, chairman of the committee of arrangements. Rev. H. W. Thomas invoked divine blessing.

Dr. Moyer introduced Judge Cavanaugh of the superior court, who, in the absence of Mayor Harrison, delivered an eloquent address on behalf of the city and State.

Dr. Frank Billings, of Chicago, followed with an address of welcome on behalf of the profession of Chicago, after which the president, Dr. Duncan Eve, of Nashville, took the chair.

The report of the secretary, by Dr. Henry E. Tuley, of Louisville, was read, which stated, among other things, that but few deaths had occurred during the year. There were three hundred members on the roll at present. Provision had been made for the issuance of a volume of Transactions this year.

The treasurer's report, by Dr. Dudley S. Reynolds, of Louisville, was also read, which showed a balance in the treasury of $133 96.

Both reports were accepted and referred for publication.

The committee on credentials, Dr. C. S. Stanton chairman, reported forty-one new members.

At this juncture, the first vice-president, Dr. A. J. Ochsner, of Chicago, took the chair, and Dr. Eve delivered his address as president, as follows:

**Malpractice and the Damage Suit.**—Strange as it may appear, he said, no systematic work gave a formal or technical definition of malpractice. He therefore had to quote from a well-known jurist on this subject: "Malpractice was the unskilful or negligent treatment of a patient by a physician or surgeon, or some one undertaking to act as such, resulting in injury to the patient." To constitute malpractice, unskilfulness and injury, or negligence and injury, to the patient must concur. The inquiry is natural, "What was meant by unskilfulness?" It was the want or absence of learning and experience in medical science. How much skill was required? The answer was "ordinary skill." What was ordinary skill? Such skill as was usually possessed by the profession at the time and place when and where the patient was treated. This was what the law termed reasonable and competent skill in medicine. The speaker said that what was ordinary skill now would have been extraordinary, wonderful, incredible skill half a century ago. In evidence of skill the practitioner had the right to prove that he was a graduate of a reputable school and to have his reputation and standing established by the evidence of his professional brethren. If a person undertook to act as a physician or surgeon, though he was neither, he was held accountable for any injury he thus caused. A patient was compelled to co-operate with his physician in the treatment of the case. He must obey instructions, no matter if to do so was painful or whatever the excuse; the physician could not be made responsible for injuries resulting from such disobedience on the part of the patient. In cases of doubt and uncertainty, in which the profession and authorities were not agreed as to treatment, the medical attendant must exercise his own best judgment. A physician could decline to attend a patient for reasons satisfactory to himself, nor was he required to give his reasons therefor. Having accepted a case, however, he must continue treatment until recovery or death terminated the relation, or the patient discharged him. Pauper patients required the same skill and diligence as pay patients. A well-known authority declared that two-thirds of the cases in which malpractice was charged arose from fractures and dislocations. Deformity was the result of many fractures and could not be prevented. Patients who had had the very best treatment for fractured collar-bones, Colles' fractures, etc., consulted with doctors until they found one who expressed an unfavorable opinion as to the plan of treatment adopted, or at least suggested that a better result could have been obtained. With this opinion, patients advised with lawyers, and a suit for malpractice was instituted. Unfortunately, enmity, jealousy, and rivalry were too often the cause of damage suits. A doctor was usually "at the bottom of it." The consent of a patient to an operation did not absolve the surgeon from responsibility; his duties and relations remained unaltered thereby. When he possessed the necessary qualifications and performed the duties required, he was not held responsible for mere errors of judgment; nor was he liable for declining professional assistance or consultation. By prescribing certain qualifications and attainments as conditions precedent to admission into the medical profession, and by defining the duties and obligations, the rights and privileges of its members, much good could be accomplished by the law-making power of the country. With this assistance the profession could the more easily establish and maintain honorable medicine, rebuke the ignorant pretender, repress empiricism, and bring to justice the presumptuous charlatan, while resisting cruel and wanton attacks upon meritorious members of the profession, and defeating vexatious and oppressive actions instituted by reckless and unscrupulous parties for purposes of speculation and persecution. Finally, the speaker urged in a forcible manner that the profession should stand as a unit by the innocent victim when unjustly attacked, as if it was a matter of personal concern to each, who should remember that when one member suffered, the reflex action was felt by all.

### SURGICAL SECTION.

**Vesico-Rectal Anastomosis.**—Dr Jacob Frank, of Chicago, read this paper. Experiments had been conducted by him on the implantation of the ureters into the rectum, which justified the conclusion that in every instance there was an ascending infection of the ureters, which terminated in the kidney. Since this was an established fact, as verified by both microscop-

ical and macroscopical study of the dogs operated on, he had every reason to believe that no better result could be attained in the human being, and from this circumstance alone the implantation of one or both ureters could never become popular. Various operators had devised different methods for the relief of exstrophy of the bladder, but Maydl's was the safest and best because, according to his technique, the ureteral openings were not anatomically interfered with; hence it was a fortification against ascending infection. Why should the ureters be cut away from a healthy bladder when it was possible for the viscus to be left almost untouched, and still accomplish the desired results? As some of the lower animals and birds had the bladder and rectum as one cloaca, the question arose, Why could not human beings live comfortably in the same condition? It was his object to place the unfortunate individual requiring this operation in the embryological state by combining the bladder and rectum into one common receptacle, from which the fæces and the urine passed. The operation consisted of anastomosing the bladder to the rectum with his decalcified bone coupler, a description of which could be found in the Medical Record, October 3, 1896, the *Journal of the American Medical Association*, June 19, 1897, and in *Medicine*, January, 1897. The technique was as follows: In a male dog the incision was made in the groin, and in a bitch in the median line. Generally the bladder was found distended, and was emptied by squeezing it gently with the hand, when the urine escaped through the natural channel. The rectum was next picked up and freed of its contents, as in any intestinal operation. The bladder and rectum were then brought forward and placed in position for anastomosis. Two or three interrupted Lembert sutures were now taken about half an inch below the lower ends of the incisions determined upon in the bladder and rectum, care being exercised in selecting them that the coupler, when it was inserted, would not encroach upon the ureteral openings. A longitudinal incision was then made in the bladder large enough for the coupler selected, and a puckering string applied over and over the cut margin. The rectum was next opened in its long axis and a puckering string similarly applied. The suture should be taken so that the free ends lay uppermost, thus facilitating easy tying. The operator now slipped the coupler into the bladder opening, at the same time gently spreading the collars apart, while an assistant made one knot and drew down on the puckering string until the rubber tubing was felt; another knot was made and the ligature cut off short. The other half of the coupler was then slipped into the rectal opening and likewise tied and cut off. Several interrupted Lembert sutures were taken around the borders to make the work more secure. The operation was simple and could be accomplished in ten or fifteen minutes. He had not yet had an opportunity of trying this new method on the human being, although it was tried on the cadaver and the technique carried out nicely. Of the fifteen dogs operated upon, ten recovered and five died. In the first two experiments the technique was imperfect and a great deal of unnecessary work was done, which undoubtedly contributed largely to the failures. As a rule, the dogs were quite sick for the first few days, and showed signs of pain, with rise of temperature. For a week after the operation urine and fæces were voided oftener than after this period. Dogs raised their legs as though in the act of urinating, without accomplishing anything, and finally squatted down and micturated from the rectum. The animals that had been kept accustomed themselves to their condition and urinated periodically. The fæces were passed in a liquid form, being softened by the urine. He believed that vesico-rectal anastomosis would not only become popular for exstrophy, but would be resorted to for other diseased conditions of the bladder, especially when a suprapubic or perineal section was performed merely for temporary relief. The field for vesico-rectal anastomosis was much larger than that for gastro-enterostomy, and the results of the former operation would be more permanent than those of the latter. One great advantage that the human being would have over the lower animal was in irrigation, as the operated parts could be kept clean with antiseptic solutions at will, thus limiting the unavoidable, but only temporary, cystitis. Another point was that the human being was kept quiet on the back after the operation; hence fæces were less liable to get into the bladder. The reverse was true of dogs. In exstrophy of the bladder the anastomosis should be made first, and the plastic operation later. Two of the dogs which were operated upon about six months ago were still alive and in good health. The result of the microscopical and bacteriological study of vesico-rectal anastomosis was much more gratifying than that of implantation of the ureters into the rectum. Dr. M. Herzog, professor of pathology in the Chicago Polyclinic, made for the essayist a number of post-mortem examinations, including a bacteriological and histological study of the material obtained from several of the dogs operated upon by the above-described method, and furnished a short abstract of his detailed report, which accompanied the paper. A uniformly striking feature of the histological examination in all cases was the very complete and firm union of the vesical and rectal tissue at the site of the anastomosis. From the report it would be noted that in only one experiment was there any macroscopical evidence of a change from the normal. If, then, the careful microscopical work had not been carried out in his series of experiments, a complete recovery could be claimed in every instance, so far as the behavior of the dog prior to the post-mortem and the appearance of the organs at the time of the post-mortem were concerned, with the exception already noted. In all his experiments of ureteral implantation an infection of the kidney resulted, and this fact led him to devise the new operation. Of all the literature accessible on ureteral implantation, few contained a microscopical report, and therefore were absolutely worthless as to kidney infection. Two points were clearly observed: First, that the recovery of the dog and the macroscopical appearance of the tissues did not necessarily signify absence of infection; second, that in the dogs killed thus far, the operation of vesico-rectal anastomosis could be performed without a resulting kidney infection.

Dr. H. O. Walker, of Detroit, commended the paper for its originality. His experience with ureteral implantation had been limited, but having read the literature on the subject, he was impressed with the practicability of the operation described by the essayist, believing that it would do away with implantation of the ureter into the rectum.

Dr. Thomas Charles Martin, of Cleveland, said that the essayist was less enthusiastic than he was justified in being, for it seemed to him that in a human subject with exstrophy of the bladder this new operation could be performed without opening the peritoneal cavity.

**Some Complications Met with Before and After Operations for Hemorrhoids; their Causes, Prevention, and Treatment.**—Dr. John L. Jelks, of Memphis, Tenn., read this paper. He reported several instructive cases. He said a surgeon sometimes in dealing with a simple rectal trouble encountered serious disease of the uterus and its adnexæ. This was particularly true when the patient was hysterical. Without the entire relief of both or all conditions, the patient would probably feel that little benefit had been

given her. Syphilis and gonorrhœa might be and often were causes of rectal troubles. When a patient with hemorrhoids had gonorrhœal infection, the latter became a serious complication, and the treatment of one or both conditions was varied by the circumstances of the case. As to tumors and pregnancy, while the latter amounted to a complication and often caused hemorrhoids, he thought as a rule only palliative treatment should be instituted. Stricture of the urethra, like cystitis, was a grave complication of hemorrhoids, or might be the cause of their development.

Dr. Joseph M. Mathews, of Louisville, believed that no intelligent surgeon to-day used carbolic acid for the treatment of internal hemorrhoids. In operating the clamp and cautery may be used, or the ligature. The former method of operating was not so liable to be followed by the complications referred to by the essayist. He would operate on hemorrhoid regardless of complications, such as pregnancy, a displaced uterus, etc.

Dr. J. R. Pennington, of Chicago, stated that hemorrhage after an operation for hemorrhoids was slight, provided the operation was thoroughly done. He disagreed with the essayist that the use of the tampon in rectal operations was a source of infection.

Dr. C. Lester Hall, of Kansas City, Mo., had never been able to devise a tampon for rectal use which did not prove a source of irritation and great pain to the patient.

Dr. Vincent J. Hawkins, of St. Paul, said the ligature method caused considerable pain in many cases, even when properly applied, and he had had to give patients hypodermics of morphine to relieve suffering.

Dr. S. B. Taylor, of Columbus, agreed with Dr. Mathews that hemorrhoids should be removed when complicating pregnancy.

Dr. H. O. Walker, of Detroit, believed that the day of the ligature had passed. He saw no reason why a surgeon should not operate for hemorrhoids the same as he did for any other condition.

Dr. Thomas Charles Martin, of Cleveland, concurred in the remarks of Dr. Walker, that the ligature, as a method of operating, should be abolished. Hemorrhoids could be removed with clamp and cautery without general anæsthesia, if the operation was properly executed.

Dr. Jelks, in closing, spoke of the value of the rectal tubular speculum devised by Dr. Pennington. He did not believe, however, that a severe hemorrhage could be controlled by a tampon during a rectal operation. Dilatation of the sphincter at the time of the operation was necessary. When he failed to divulse the sphincter or to dilate thoroughly the rectum, the patient always suffered more or less pain.

**The Mastoid Operation.**—This paper was read by Dr. George F. Keiper, of Lafayette, Ind. He reported several cases. He directed attention to the possible injury of the facial nerve in operative work either upon the mastoid or the middle ear. He believed that surgeons had been reckless in this regard and patients had suffered in consequence. If the facial nerve is wounded or cut off, all authorities were agreed that it could not be regenerated in less time than from twelve months to two years, if regenerated at all; hence the importance of taking due notice of its presence in operative work. Wounding of the facial nerve was liable to take place, notwithstanding every precaution that might be taken. A case operated upon by the essayist showed partial facial paralysis because, he believed, the facial nerve was misplaced.

Dr. William L. Ballenger, of Chicago, condemned the use of the trephine for beginning a mastoid operation. He considered the chisel a better instrument, or the dental engine with a bur, or the Russian perforator.

**Modern Surgical Treatment of Hemorrhoids.**—Dr. Gustavus M. Blech, of Chicago, contributed this paper. Since a hemorrhoidal tumor was but the result of an inflammatory process, the author believed that germ infection must be the main etiological factor. A locus minoris resistentiæ was produced by certain mechanical influences, which, however, in the light of modern pathology could be considered only as predisposing causes. In this class belonged straining during defecation, obstruction of the portal vessels from liver disease and abdominal tumors, pressure produced by the gravid uterus, pressure on the veins from impacted fæces, etc. That germs were primary factors in the production of hemorrhoids, the author was satisfied from observations in his practice. Coming to the treatment, he said that in the earlier years of his professional career he was in the habit of removing internal and external hemorrhoids with the écraseur. His objection at present to this method was that the wire of the instrument was very apt to break, leaving the operator in a dilemma, especially when the operation was half done. Secondly, the cut surface was neither accurate nor could it be regulated. No matter how close the wires were kept down to the base, the écraseur cut as it pleased, and not as the surgeon desired it. Thirdly, it frequently happened that, after the operation was completed, complete separation of the tissues did not take place, and if the screw was tightened some tissue was drawn into the stem, and if the tightening was continued the stem was apt to bore itself into the rectal wall. The author did not favor the Whitehead operation. His method of operating for internal hemorrhoids differed but little from the one in vogue by most surgeons. If he had to remove but one tumor of large size, he simply threw around its base a temporary ligature, cut off the entire tumor, and then sewed the wound in the direction of the axis of the rectum with interrupted sutures

Dr. F. F. Bryan, of Georgetown, Ky., said that he operated with clamp and cautery, and with the ligature, but considered the former a more popular method, and he advised its use in every instance in which there was no contraindication. He had not met with a case in which there were contraindications to its use.

Dr. Jelks, of Memphis, said there was no more pain after the use of the clamp and cautery than after the ligature. He seldom encountered hemorrhage after the application of the ligature.

Dr. Blech, in closing, agreed with Dr. Jelks as to the painlessness of the ligature method in treating hemorrhoids. He had known patients to complain bitterly after treatment with the thermo-cautery, so that it was necessary to give rectal suppositories of morphine, etc., to afford relief.

**Beta-Eucaine as an Anæsthetic in Eye, Nose, and Throat Work.**—Dr. William H. Poole, of Detroit, read this paper, in which, after reporting a series of cases in which this agent was used, he drew the following conclusions: (1) Eucaine was decidedly less toxic than cocaine, therefore it was superior to it. (2) Its aqueous solutions kept well and could be sterilized by boiling without destroying the activity of the drug. (3) It produced anæsthesia equally well and sometimes better than cocaine. (4) It was superior to cocaine, in that it caused no heart depression or other unpleasant systemic effect. (5) It caused no mydriasis, and no disturbance of accommodation, which was an advantage in some cases. (6) It was less dangerous to the cornea than cocaine, inasmuch as it did not cause a desquamation of the superficial epithelium.

**Intolerant Ulceration of the Rectum.**—A paper on this subject was read by Dr. Sterling B. Taylor

of Columbus, Ohio, in which the author reviewed the surgical anatomy of the anal portion of the rectum at considerable length. In the early stages of intolerant ulceration, physicians were inclined to discredit the presence of any severe pain, inasmuch as in its incipiency it was merely a rent or tear in the mucous membrane. This was prevented from healing by the lodgment of small particles of fecal matter, which produced irritation and inflammation and eventually painful ulceration. The extreme pain made its appearance with the unhealthy granulations. Pain was not the only disagreeable accompaniment, as there was often annoying and sometimes dangerous hemorrhage, especially if the ulcer was located high. The usual seat of the ulcer was at the posterior commissure, and it was here that it was most painful. The anterior commissure was the next favorite seat of the ulcer. In the treatment, the essayist recommended the method practised by Martin, which he considered simple and effective. No general anæsthesia was required, but simply infiltration anæsthesia, which was effected by the injection of a few drops of a one-tenth of one per cent. solution of eucaine or cocaine around the ulcer. A slight incision was then made through the membrane and integument down to, but not through, the sphincter. The operator then packed with a small piece of iodoform gauze. The bowels should be kept open with some laxative, preferably a mineral water. Apenta water was both pleasant and efficacious. Several cases were reported in which the Martin method of treatment was resorted to. Dr. Taylor held that rectal ulcers could be excised under eucaine anæsthesia without pain.
